13.4—Malabsorption Syndromes and Maldigestion: Pathophysiology, Assessment, Management, and Outcome

Malcolm C. Roberts

13.4.1

Pathophysiology

Malabsorption and maldigestion are recognized clinical problems in human medicine. In the horse the clinician often reaches the diagnosis of malabsorption for a condition by exclusion in the workup of a horse with chronic weight loss and wasting. The term *malabsorption* implies impairment of digestive and absorptive processes arising from functional or structural disorders of the small intestine and related organs, the pancreas, liver, and biliary tract. The condition can affect absorption of carbohydrates, proteins, fats, vitamins, minerals, and to a lesser extent, water and electrolytes. In the horse the resulting pathophysiologic changes may influence large intestinal function adversely through alterations in the substrate presented for fermentation. Malabsorption syndromes are encountered more frequently in human beings and small animals than they are in horses. 796

797

One should direct the clinical investigation of malabsorption at ascertaining and trying to localize the source of the abnormality. In medical practice, impairment of one or more phases of the digestion and absorption of dietary constituents may precipitate clinical signs that are associated primarily with carbohydrate, protein, or fat malabsorption. This level of differentiation is not possible in the horse because of the herbivorous diet and the contribution of large intestinal functions.

In human and small animal medicine, disturbances in digestive processes especially from exocrine pancreatic insufficiency or reduced intestinal bile salt concentration are principal determinants of many clinical

malabsorption syndromes. The rarity of pancreatic problems in horses and the herbivorous diet makes maldigestion less of a concern and difficult to pursue diagnostically. Nevertheless, maldigestion undoubtedly contributes to chronic weight loss conditions in horses, which may be significant with severe infiltrative disease of the small intestine with partial to total villous atrophy and flattened mucosa. Impairment of digestive processes may exacerbate diarrhea in the suckling foal through reduced intestinal bile salt concentrations from hepatic or ileal dysfunction.

Malabsorption is not synonymous with diarrhea, although diarrhea may be a feature. Adult horses rarely exhibit diarrhea with small intestinal problems unless large intestinal involvement is concomitant. Chronic diarrhea is predominantly a large intestinal disorder that reflects an overload of water and electrolytes and thus may be considered a state of impaired absorption. Primary small intestinal disease is more likely to occur in neonates and young foals. For example, acquired small intestinal brush border lactase deficiency may result in increased lactose fermentation in the large intestine and induction of osmotic diarrhea.[1] Box 13.4-1 lists conditions that have been or potentially could be associated with malabsorption syndromes and maldigestion in the horse.

13.4.1.1

BOX 13.4-1 CONDITIONS THAT HAVE BEEN OR COULD BE ASSOCIATED WITH MALABSORPTION SYNDROMES AND MALDIGESTION IN THE HORSE

13.4.1.1.1

Malabsorption

13.4.1.1.1.1

Inadequate absorptive surface area

- Small intestinal resection (short bowel syndrome), villous atrophy (idiopathic), and mucosal atrophy

13.4.1.1.1.2

Small intestinal bacterial overgrowth (ileocecal valve bypass; physiologic)

13.4.1.1.1.3

Inflammatory or infiltrative disorders: chronic inflammatory bowel disease

- Granulomatous enteritis
- Multisystemic eosinophilic epitheliotropic disease (includes all eosinophilic conditions, such as eosinophilic granulomatosis, chronic eosinophilic gastroenteritis, and chronic eosinophilic dermatitis, except eosinophilic enterocolitis)
- Basophilic enterocolitis
- Lymphocytic-plasmacytic enterocolitis
- Lymphosarcoma, alimentary form; other forms with alimentary involvement
- Amyloidosis

13.4.1.1.1.4 Parasitic causes (larval cyathostomes)

13.4.1.1.1.5 Infectious causes (response to infectious agents)

- *Mycobacterium* spp., *Rhodococcus equi, Salmonella* spp., *Lawsonia intracellulare* (proliferative enterocolitis), *Histoplasma* spp., and others

13.4.1.1.1.6 Immunologic causes

- Immediate hypersensitivity to antigens presented to or absorbed from intestinal tract; food allergy

13.4.1.1.1.7 Biochemical defects (with or without microscopic cellular damage)

- Disaccharidase deficiency: acquired lactase deficiency in foals and monosaccharide transport defects

13.4.1.1.1.8 Lymphatic obstruction

- Lymphadenopathy; lymphangiectasia abscesses

13.4.1.1.1.9 Miscellaneous

- Partial intestinal obstruction, adhesions, mural thickening, and toxin-induced

13.4.1.1.2 Maldigestion

13.4.1.1.2.1 Gastric disorders

- Deficiency or inactivation of pancreatic lipase
- Exocrine pancreatic insufficiency: chronic pancreatitis and pancreatic carcinoma

13.4.1.1.2.2 Reduced intestinal bile salt concentration (with impaired lipid micelle formation)

- Hepatic dysfunction: parenchymal liver disease and cholestasis
- Interrupted enterohepatic bile circulation; ileal inflammatory disease or resection
- Abnormal bacterial proliferation in the small intestine: stagnant (blind) loops, incompetent ileocecocolic valve, bypass and resection, and hypomotility
- Drug-induced sequestration of bile salts: neomycin and calcium carbonate
- Small intestinal brush border enzyme deficiency

797

798

Malabsorption in horses has no pathognomonic clinical syndrome. Case recognition derives from the robust investigation of horses with chronic wasting. Prevalence is unknown. No strict case definition exists, even for

chronic wasting. Interest generated by unusual clinical test results and their related pathologic findings has stimulated publication of reports of cases considered as malabsorption in horses. Pathologic description of the predominant cellular infiltrate and the pattern of intestinal distribution have resulted in the classification of many conditions as representing examples of chronic inflammatory bowel disease (CIBD) (see Box 13.4-1), drawing analogies from human medicine. In the affected animal, coexistent enteric protein loss reflecting changes in mucosal integrity from extensive infiltration and inflammation in the intestinal tract is likely to be more debilitating than the malabsorption.

13.4.2 Clinical Assessment

The principal concern of the owner is the weight loss and poor condition of the horse. Many clinical examination findings, except for body condition, may appear within normal limits. Investigation of the weight loss, together with the clinical pathologic findings, helps to eliminate other more commonly encountered causes of wasting. Box 13.4-2 lists clinical signs that may be associated with malabsorption syndromes.

13.4.2.1 BOX 13.4-2 CLINICAL SIGNS THAT MAY BE ASSOCIATED WITH MALABSORPTION SYNDROMES

Vital signs usually within normal limits: occasional slight fever, diurnal or cyclic (inflammation)

Mucosa: pallor; chronic anemia

Appetite: anorexia; poor, normal, or ravenous

Body condition: weight loss, chronic wasting, or more rapid and dramatic decline

Demeanor: normal, dull, or depressed

Energy and activity level: normal, decreased, or lethargic

Fecal consistency: formed, scant, increased, or diarrhea

Large intestinal involvement: diarrhea, unstructured feces, or blood

Pain: persistent low grade or intermittent abdominal discomfort

Edema: reduced albumin absorption, enteric protein loss, lymphatic obstruction, or liver disease

Palpable rectal abnormalities: thickened bowel wall or enlarged mesenteric lymph nodes

Extraintestinal signs: generalized skin lesions, exudative dermatitis, ulcerative coronitis, or arthritis

No characteristic clinical pathologic profile of malabsorption exists. Findings relate to the stage of the underlying disease process and intercurrent problems. The syndrome tends to cause anemia (normocytic, normochromic) and neutrophilia. Hemolytic or macrocytic anemia and thrombocytopenia have been observed in alimentary lymphosarcoma. Lymphocytosis (leukemia) rarely is encountered. Eosinophilia is uncommon even with suspected immune-mediated conditions and widespread tissue eosinophilia. Many animals are hypoalbuminemic and hypoproteinemic; horses with alimentary lymphosarcoma may exhibit hyperproteinemia and hypergammaglobulinemia. Serum or plasma may be lipemic. The clinician may find elevated hepatic and biliary

tract enzymes (γ-glutamyltransferase and alkaline phosphatase) in multisystemic conditions; for example, eosinophilic granulomatosis (multisystemic eosinophilic epitheliotropic disease; EG [MEED]). Abdominocentesis has been of diagnostic value in several alimentary lymphosarcoma cases, but rarely in the granulomatous conditions.

Ultrasonographic examination of the abdomen can yield infomation on intestinal distention, wall thickness, and unexplained masses detected on rectal palpation. Rectal biopsy is easy to perform and may provide an indication of cellular infiltration that could be present at more proximal locations. However, pathologists examine few equine rectal samples, and the interpretation is frequently equivocal. Adoption of standardized grading or classification would improve the diagnostic value. A proposed classification system was based on a retrospective study of 130 rectal biopsies from 116 horses ages 1 to 18 years with clinical signs of intestinal disease. Necropsy results were studied from 40 horses. Biopsy specimens (21 horses) and necropsy rectal tissue (9 horses) from 30 horses ages 4 to 22 years served as controls. Simple proctitis, the presence of neutrophils in the crypt or surface epithelium, was an abnormal finding compared with mild scattered neutrophil infiltration in controls. Simple proctitis was found in association with malignant lymphoma and other inflammatory disorders. Inflammatory bowel disease was diagnosed from rectal biopsy specimens in 6 of 12 EG (MEED) cases and 4 of 9 granulomatous enteritis cases confirmed at necropsy.[2] Rectal biopsy aided diagnosis for 3 of 7 horses in a series of lymphocytic-plasmacytic enterocolitis cases.[3] Eosinophils were demonstrated on impression smears of rectal mucosal biopsies from 1 of 2 horses with eosinophilic enterocolitis.[4]

Skin biopsies or ultrasound-guided biopsies of liver, lymph node, or lung may reveal evidence of multisystemic disease. One can obtain intestinal and lymph node biopsies via a standing laparotomy. Exploratory laparotomy 798
facilitates rigorous inspection of the gastrointestinal tract and associated organs to obtain multiple biopsies from 799
intestinal sites and lymph nodes. The procedure may provide a diagnosis, enabling one to make decisions on potential treatment and management options. Cost and potential postoperative complications may limit surgical procedures for diagnosis. Laparoscopy may provide an alternative means to facilitate biopsy of certain tissues. However, one should consider surgical exploration as an option early in the process rather than as a last resort.

The noninvasive breath hydrogen test used to assess carbohydrate malabsorption in human beings has not proved reliable in equine studies.[5]

13.4.2.2 CARBOHYDRATE ABSORPTION TESTS AND INTESTINAL FUNCTION TESTS

Intestinal function tests can provide a practical and inexpensive means to assess the absorptive capability of the small intestine. For clinical practice purposes this is limited to carbohydrate absorption. Abnormality of carbohydrate absorption has become an important precept on which to base a diagnosis of malabsorption in the horse. However, results of the oral glucose tolerance test (OGTT) or d-xylose absorption test require cautious interpretation. Pathologic changes in the mucosa and submucosa must be extensive and widely distributed to greatly affect the peak plasma concentration and shape of the curve. The tests are easy to perform in practice and require a baseline blood sample predosing and further samples for up to 6 hours after administration of the solution. Many commercial laboratories conduct glucose and xylose assays.

13.4.2.2.1 Oral Glucose Tolerance Test

The immediate dietary history, gastric emptying rate, intestinal transit, age, and hormonal effects of the horse influence glucose peak and curve shape. Higher glucose peaks are recorded from healthy animals eating grass or hay than from those eating concentrates. Recent appetite or the level of cachexia may affect

test results. Maximum plasma glucose level (>85% baseline) is reached by 120 minutes in healthy animals given 1 g glucose per kilogram body mass as a 20% solution.[6,7] Break points below which the probability increases of carbohydrate malabsorption associated with intestinal morphology changes have been proposed.[7]

A referral population of 42 mature horses with chronic weight loss was divided into three groups based on OGTT results to determine if any concurrence with the morphologic diagnoses existed. Group 1 ($n = 5$) had a normal OGTT (peak glucose concentration at 120 minutes >85% baseline) and contained animals that had normal small intestinal morphology, and a few with large intestinal lesions. Group 2 ($n = 25$) had partial malabsorption and included 18 horses with small intestinal infiltrative disease that allowed some glucose uptake. Diagnoses included lymphosarcoma, villous atrophy, granulomatous enteritis and EG (MEED). Seven horses had normal small intestinal histologic findings. Peak glucose concentrations were less than 85% and greater than 15% of baseline at 120 minutes. Seventeen horses in the group had large intestinal pathologic conditions. Group 3 horses ($n = 12$) had total malabsorption; the peak concentration at 120 minutes was less than 15% above baseline. These horses had severe infiltration throughout most of the small intestine that was attributed predominantly to lymphosarcoma or granulomatous enteritis.

However, the test is far from definitive; one cannot assume a flat curve indicates malabsorption and a poor prognosis. Two horses with chronic weight loss initially diagnosed with malabsorption based on flat OGTT curve s subsequently showed more normal OGTT responses.[8] Full-thickness intestinal biopsies were unremarkable. One horse had an elevated serum immunoglobulin E to oat allergen. Oats and oat straw were removed from access. Dexamethasone was given on a tapered protocol, and a repeat OGTT was normal at 18 months. The other horse received oral probiotics to counter suspected small intestinal bacterial overgrowth, was clinically normal in 2 months, and had an improved OGTT with a 60 minute peak. Therefore malabsorption, as defined by an absorption test and weight loss, may occur in the horse without significant morphologic changes in the intestine, and the condition may be transient. Demonstration of carbohydrate malabsorption in 16 of 24 horses with chronic diarrhea showed poor diagnostic sensitivity for small intestinal involvement. Impaired glucose absorption was recorded in horses with predominantly large intestinal problems, cyathostomiasis, chronic colitis, alimentary lymphosarcoma, and MEED.[9]

13.4.2.2.2 D-Xylose Absorption Test

Although prior dietary history influences peak plasma xylose concentration, xylose is not confounded by hormonal effects or mucosal metabolism. Gastric emptying rate, intestinal motility, intraluminal bacterial overgrowth, and renal clearance do affect curve shape. Healthy mares not fed for up to 96 hours had flatter curves and a slower decrease in plasma xylose than when deprived for 12 to 36 hours.[10] Hence recent appetite or the level of cachexia may influence test results.

Abnormal d-xylose absorption represented by a flat curve or delayed absorption is considered indicative of significant jejunal disease and has been observed with most examples of CIBD, parasitism, and idiopathic villous atrophy.[11,12] Ponies may have lower peak d-xylose concentrations at 60 and 90 minutes than horses, although the range of peak values at the test dosage (0.5 g D-xylose per kilogram body mass in a 10% solution) is wide. 799

800 Potentially diagnostic discriminatory cut off points for peak plasma xylose concentrations have not been determined.

Abnormal absorption curves have been detected in the absence of small intestinal histologic changes,[13] and interpretation is clouded further by findings from small intestinal resection studies in healthy ponies. Nine

ponies with 70% distal small intestinal resection and four sham-operated controls were placed on interval feeding for 5 weeks and then turned out to pasture until 6 months after surgery. Grazing was supplemented by twice daily (meal feeding) concentrate rations. All ponies gained weight and were clinically normal, and none developed diarrhea. However, the mean peak xylose concentration at 60 minutes declined progressively (at monthly intervals) over the study period in the resection group to 15% of that of controls. Lack of clinical malabsorption was attributed to adaptation of the residual 30% of healthy small intestine and of large intestinal function.[14] Bacterial overgrowth in the small bowel remnant from refluxed cecal contents (resected ponies had ileocecal valve bypass) may have contributed to the abnormal xylose assimilation. By contrast, xylose absorption decreased over 6 months, associated with substantial weight loss, lethargy, and diarrhea, in an earlier study of extensive (≥60%) small intestinal resection in ponies.[15] An important difference was the feeding pattern; those ponies received pelleted feed twice daily for the entire 6 month follow-up period.

Consequently, horses with suspected malabsorption may adapt to an interval feeding regimen. The critical factor could be the availability of sufficient unaffected or minimally affected small intestine and large intestinal functional capacity. The outcome for animals with small intestinal disease and some unknown degree of large intestinal pathologic dysfunction may be less successful than shown in the experimental study.

Abnormal xylose absorption reverted to normal following 35 days of corticosteroid therapy in an adult Thoroughbred gelding with a 6-week history of weight loss and diarrhea for 3 weeks; peak xylose concentration at 60 minutes was within normal limits and the horse had gained weight.[4] d-xylose absorption was abnormal in an adult Standardbred gelding with a 2-month history of poor performance, weight loss, intermittent fever, mesenteric lymphadenopathy, elevated fibrinogen, and decreased albumin and globulin levels. Multiple full-thickness small intestinal biopsies revealed evidence of granulomatous enteritis. The horse received antibiotics postoperatively and then corticosteroids parenterally for 4 to 5 months. After 3 weeks, peak plasma xylose had increased, although absorption was delayed. Five months after cessation of corticosteroid therapy, the horse had regained weight and was bright and alert, and d-xylose absorption was normal.[16]

Diagnostic predictions were made retrospectively by examining d-xylose absorption in horses with granulomatous enteritis compared with those with EG.[17] Peak xylose concentrations were much lower in horses with granulomatous enteritis than those with EG, whereas in EG the absorption curve shifted to the right with the peak occurring at 240 minutes. The small intestine is affected predominantly in granulomatous enteritis with extensive villous atrophy and more diffuse lesions in the large intestine, whereas in EG (MEED) the large intestine is more involved. Hence, the extent and distribution of pathologic changes in the small and large intestines may influence xylose absorption test results.

13.4.3 Management, Therapy, and Outcome

The chronic wasting horse with suspected malabsorption and probable enteric protein loss has at best a guarded to poor prognosis. Prognosis may be improved through early and aggressive investigation to achieve a diagnosis, and perhaps assess the stage in the natural progression of the disorder. The owner may elect euthanasia of the animal or may be willing to determine whether the condition can be improved. In the short term, intravenous infusion of plasma or colloids, with or without fluids and electrolytes, may be necessary to stabilize the condition. Prognosis is much worse for the horse that is inappetent. Prolonged intensive total parenteral nutrition and/or oral alimentation may not be a realistic course of action. The overall therapeutic and management plan

can prove to be expensive. The owner must be cognizant from the start that the outcome may not be altered, even after protracted therapy. One cannot make predictions for outcome of therapy without meaningful data because only a few case reports of successful responses with long-term follow up exist.

13.4.3.1 NUTRITION

Some level of digestive and absorptive capability remains in the diseased small intestine. Interval feeding of small quantities of food may be beneficial if the horse continues to eat, and particularly for animals with ravenous appetites that seem able to maintain their reduced state of body condition without further losses. Diet should include feeds with a high fiber content to favor large intestinal fermentation, including grass hay and access to pasture complemented by commercial high-fiber rations based on beet pulp and soybean hulls. Energy intake can be increased through feeding high-energy dense fats that provide 2.25 times more calories than carbohydrates. Most affected horses should tolerate high fat (5% to 10%) processed feeds containing vegetable oils or rice bran (up to 20% of the concentrate mix, equivalent to 8% vegetable oil) to achieve the 800
higher-fat composition. Changeover to a higher-fat concentrate should be gradual. Even in healthy animals 801
that can eat up to 20% added fat, appetite may decrease as the percentage increases, and fecal consistency may change. Clearly, the objective for the horse with suspected malabsorption is to sustain, and preferably increase, dietary intake, value, and efficiency.

The owner of an affected horse must be prepared to experiment with feeds, must be patient, and must keep records. No standard procedure exists. Exposure to a feed component may contribute to the problem as an allergen eliciting a hypersensitivity reaction. Identifying the potential allergen through immunologic testing or by stepwise removal and outcome assessment over a longer period may be difficult. The clinician should give immunosuppressive drugs early in the process.

13.4.3.2 DRUG THERAPY

Immunosuppressive agents have produced the most promising responses to ameliorate the effects of conditions associated with malabsorption, particularly CIBD. Short-duration, and in some cases more prolonged and sustained, improvements in body condition, weight gain, demeanor, energy and activity levels have occurred following corticosteroid administration. One should start treatment as early as possible. One should follow initial parenteral (intramuscular or intravenous) loading doses of dexamethasone (sodium phosphate) with a series of depot injections, or orally administered prednisolone or prednisone, on a tapered dose protocol over a period of months. Interval low-dose therapy may be necessary if clinical signs return after treatment ends. One uses the lowest dose to control the clinical signs for alternate-day therapy. Clinical benefits far outweigh concerns over potential adverse effects. Chemotherapeutic agents such as vincristine, cytosine, cyclophosphamide, and hydroxyurea have been tried in a few cases of CIBD or lymphosarcoma with no apparent success, probably related to the advanced stage of the disease when treatment was initiated and the dose selected.

13.4.3.3 SURGERY

Resection of a segment of intestine that is edematous, hemorrhagic, or constricted is an option in localized forms of CIBD,[18,19] particularly if gross changes are not discernible in adjacent or distant parts of the intestinal tract, that is, malabsorption is not a feature. Long-term outcome has been favorable. Removal of a substantial proportion of the diseased small intestine may be indicated in a horse with malabsorption, considering that resection of 70% distal small intestine was performed in healthy animals without inducing

adverse effects. However, because pathologic changes may exist in normal-appearing small or large intestine that is not resected or biopsied, the prognosis remains guarded. Two young horses with granulomatous enteritis had the thickened terminal small intestine resected with positive outcomes; one survived 4 months, the other has a follow up extending more than 10 years.[20]

13.5—Pathophysiology of Mucosal Injury and Repair

Anthony T. Blikslager

801

802

13.5.1

Mucosal Barrier Function

To gain an appreciation of the mechanisms whereby the mucosa is injured and subsequently repaired, one must understand how the integrity of the mucosa is regulated physiologically. Regulation of mucosal integrity is referred to as mucosal barrier function, which is vital because it prevents bacteria and associated toxins from gaining access to subepithelial tissues and the circulation. However, the mucosa has two conflicting functions: it must serve as a protective barrier and continue to absorb solutes necessary to maintain well-being of the host. This conflict is most notable at the intercellular (paracellular) space, which allows passage of select solutes and water,[1–4] but which does not admit large molecules, including bacterial toxins.[5] The paracellular space is regulated almost exclusively by the tight junction,[6] which is the interepithelial junction at the apical-most aspect of the paracellular space. Although these tight junctions originally were viewed as inert cellular adhesion sites, what has become clear in recent years is that tight junction permeability depends on tissue-specific molecular structure and is regulated by a complex array of intracellular proteins and the cytoskeleton. Tight junctions consist of a group of transmembrane proteins that interdigitate from adjacent cells. Although occludin originally was thought to be the predominant tight junction transmembrane protein, a group of proteins termed *claudins* appear to be more critical.[7] These transmembrane proteins interact with the cytoskeleton via a series of intracellular proteins, including zonula occludens 1, 2, and 3; cingulin; and others.[8] In addition, local regulatory proteins such as the small guanosine triphosphatase-Rho are also critical to tight junction function. In general the relative contractile state of the actin cytoskeleton determines the degree to which tight junctions are open or closed, but the complexities of regulation of this process are understood poorly.[9,10]

The most sensitive measure of mucosal barrier function is transepithelial electric resistance, which is measured by mounting mucosa in an ex vivo system called an Ussing chamber, because this measurement is largely a reflection of the permeability of mucosa to ions.[11,12] Ions may follow one of two routes when traversing epithelium: transcellular and paracellular.[5] Because cell membranes have a resistance to passive flow of ions 1.5 to 3 log units greater than that of the epithelium as a whole, measurements of transepithelial resistance largely reflect the resistance of the paracellular space, and in particular the tight junctions that regulate paracellular flow of ions.[12] Because tight junctions differ in structure from different portions of the mucosa,[13] measurements of transepithelial resistance reflect the net resistance of epithelium of variable permeability within a given tissue. For example, tight junctions in the intestinal glandular structures called crypts are leakier than those in the surface epithelium because of fewer and less organized tight junction strands.[11,14] Conversely, surface epithelium has a greater number of well-organized tight junction strands that result in epithelium with a high resistance.[11] This correlates well with the absorptive function of epithelium located on the mucosal surface and the secretory function of crypt epithelium. Structure of tight junctions also varies with the segment of intestine. For example, tight junctions have more strands in the ileum than in the jejunum, which is reflected by a higher transepithelial resistance in the ileum.[15]

13.5.1.1

GASTRIC MUCOSAL BARRIER FUNCTION

The stomach has four regions based on the type of mucosal lining (in an orad to aborad order): nonglandular stratified squamous epithelium, cardiac epithelium, proper gastric mucosa, and pyloric mucosa.[16] Stratified squamous epithelium has distinct differences in terms of barrier function compared with the remainder of the gastrointestinal tract. This epithelium has baseline transepithelial resistance measurements of approximately 2000 to 3000 Ω/cm[2], which is an order of magnitude higher than the adjacent cardiac mucosa.[17,18] Thus the stratified squamous mucosa is exceptionally impermeable. This in effect is the only mechanism this mucosa has to defend itself against injury. The stratified squamous epithelium consists of four layers: the outer stratum corneum, stratum transitionale, stratum spinosum, and the basal stratum germinativum. However, not all layers contribute equally to barrier function, the barrier being composed mostly of interepithelial tight junctions in the stratum corneum and mucosubstances secreted by the stratum spinosum.[17,19] The relative impermeability of stratified squamous mucosa can be demonstrated by the effects of HCl on this type of epithelium in vitro, which has little effect until it reaches a pH of 2.5 or lower.[18] Thus although most of the literature on equine ulceration pertains to the effects of HCl and inhibitors of HCl secretion,[20–23] other factors may be critical to the development of gastric ulcer disease.

The site of HCl secretion (proper gastric mucosa) also is protected from so-called back-diffusion of H^+ by a high transepithelial electric resistance (compared with cardiac mucosa), but a number of other critical mechanisms also exist to prevent acid injury. The gastric mucosa secretes mucus and bicarbonate, which together form a HCO_3^--containing gel that titrates acid before it reaches the lumen.[24,25] The mucus layer is formed principally by glycoproteins (mucins) secreted by goblet cells but also includes other gastric secretions and sloughed epithelial cells. Mucins consist of core peptides with a series of densely packed O-linked polysaccharide side chains that, once secreted, become hydrated and form a viscoelastic gel. However, the mucus layer does not form an absolute barrier to back-diffusion of acid. Thus for acid that does back-diffuse into the gastric mucosa, epithelial Na^+/H^+ exchangers are capable of expelling H^+ once the cell reaches a critical pH.[25]

802

803

Recent studies have renewed interest in the protective mechanisms of mucus because of the discovery of a group of compounds secreted by goblet cells called trefoil peptides. The name of these peptides is derived from a highly conserved cloverleaf structural motif, which confers substantial resistance to degradation by proteases including pepsin. Three members of this group are known, pS2, SP, and intestinal trefoil factor, the latter of which is secreted solely by goblet cells in the small and large intestine. pS2 and SP are secreted by goblet cells within the stomach and are believed to intercalate with mucus glycoproteins, possibly contributing to the barrier properties of mucus.[26] These peptides also play a critical role in repair of injured mucosa.

An additional mucosal function that serves to reduce the level of injury is adaptive cytoprotection, wherein application of topical irritants to gastric mucosa results in subsequent protection of mucosa in response to repeated exposure to damaging agents. For example, pretreatmen t with 10% ethanol protected against mucosal damage in response to subsequent application of absolute ethanol, and this effect was abolished by treatment with the cyclooxygenase inhibitor indomethacin.[27] The cytoprotective effect of prostaglandins has been demonstrated directly in studies in which preadministration of prostaglandins protected gastric mucosa from damage by agents such as concentrated HCl and hypertonic saline.[28] Prostaglandins appear to be cytoprotective in the stomach at doses less than those used to inhibit gastric acid secretion, ruling out a simple

antacid mechanism.[29] Although not fully characterized, cytoprotection has been attributed in part to prostaglandin-stimulated mucus production.[30] An associated beneficial effect of prostaglandins is the increased production of bicarbonate, which is trapped within mucus on the surface of the mucosa.[31,32] Interestingly, prostaglandin E_2 (PGE_2) appears to lose its cytoprotective activity in the presence of the mucolytic agent *N*-acetylcysteine. Attention also has been directed at enhanced mucosal blood flow as a potential mechanism for prostaglandin-mediated cytoprotection. For example, pretreatment with PGI_2 protected against ethanol-induced mucosal damage as a result of increased mucosal blood flow.[33] Although PGE_2, which is also cytoprotective, does not increase blood flow,[34] it may prevent vascular stasis associated with irritant-induced vascular damage resulting from inhibition of neutrophil adherence to damaged endothelium.[35]

Sensory nerves also have been implicated in cytoprotective mechanisms. These nerves are distributed throughout gastrointestinal mucosa. As an example of their importance in mucosal cytoprotection, pretreatment of newborn rats with capsaicin (to which sensory nerves are sensitive) renders the mature rats more susceptible to gastric injury.[36] Alternatively, use of a low dose of capsaicin, which stimulates rather than destroys sensory nerves, protects gastric mucosa against injurious agents.[37,38] Sensory nerves contain neuropeptides such as calcitonin–gene-related peptide (CGRP) and substance P, which may play a protective role via vascular mechanisms. For instance, CGRP stimulates increased gastric blood flow, which is theorized to reduce injury in much the same way as prostaglandins do. In fact, recent studies suggest that the roles of prostaglandins and CGRP in gastric cytoprotection are intertwined intimately. In particular, PGI_2 is believed to sensitize sensory nerves following treatment with a mild irritant, with resultant increases in CGRP release and mucosal flow. Similar studies have shown that antagonists of CGRP inhibit the cytoprotective action of PGE_2.[39] Another neural mediator, nitric oxide, also has been implicated in adaptive cytoprotection. Interestingly, nitric oxide has a number of actions that are similar to those of prostaglandins, including maintenance of mucosal blood flow.[40]

13.5.2 Intestinal Barrier Function

Regulation of barrier function in the intestine is not as well characterized as that of the stomach, although mechanisms of barrier function, including secretion of mucus and regulation of mucosal blood flow, are presumed to be similar. The proximal duodenum also has to protect itself from acid damage as it receives gastric contents, and this involves secretion of mucus and bicarbonate in much the same way as the stomach. One other mechanism that helps the stomach and the intestine to maintain mucosal barrier function is the speed with which the mucosa repairs. Thus for a defect to develop in the mucosal barrier, injurious factors have to outpace mucosal recovery. Such recovery initially involves epithelial migration across denuded regions of basement membrane 803
(restitution),[26] a process so rapid that epithelial defects may be resurfaced within minutes. For example, in bile 804
salt–injured colon, denuded surface mucosa was covered completely by restitution.[41] In the small intestine, villi greatly amplify the surface area of the mucosal luminal surface, which in turn takes far longer to resurface with restituting epithelium once it has become denuded.[42] However, intestinal villi are able to reduce the denuded surface area considerably by extensively contracting.[43] These mechanisms are described in detail under Mechanisms of Gastrointestinal Mucosal Repair.

13.5.3 Mechanisms of Gastric Injury

13.5.3.1 ULCERATION OF STRATIFIED SQUAMOUS MUCOSA

Although the stratified squamous epithelium is relatively impermeable to HCl, a number of factors can enhance the damaging effects of HCl in this epithelium. In particular, bile salts and short-chain fatty acids are capable of breaking down the squamous epithelial barrier at an acid pH, thereby exposing deep layers to HCl, with subsequent development of ulceration.[18,44] High concentrations of short-chain fatty acids normally exist within the equine stomach because of microbial fermentation.[17] These weak acids penetrate squamous mucosa and appear to damage Na^+ transport activity principally located in the stratum germinativum. Bile salts also may be present in the proximal stomach because of reflux from the duodenum. Although such reflux has a high pH, bile salts appear to adhere to stratified squamous epithelium, becoming lipid soluble and triggering damage once the pH falls below 4.[45] Diet and management (e.g., periods of fasting) also play crucial roles in the development of conditions conducive to gastric ulceration. Typically, a pH gradation in horses exists from proximal to distal compartments of the stomach, with the lowest pH values in the distal stomach.[46] However, fasting disrupts this stratification such that low pH values may be recorded in the proximal stomach.[47] Fasting conditions also increase the concentration of duodenal contents within the proximal stomach, particularly bile.[45]

13.5.3.2 ULCERATION OF PROPER GASTRIC MUCOSA

Proper gastric mucosa is exposed to injurious agents, including pepsin, bile, and acid. Parietal cells in the horse secrete acid constantly as an adaptation to near-continuous intake of roughage,[16] but the enterochromaffin-like cells within the proper gastric mucosa and G and D cells within the pyloric mucosa tightly regulate acid secretion. Histamine released by enterochromaffin-like cells amplifies acid secretion and interacts with H_2 receptors on parietal cells and G cells, which release the prosecretory hormone gastrin. A combination of histamine and gastrin can have a synergistic effect on parietal cell gastric secretion, because these mediators have distinct receptors and second messengers. However, D cells are sensitive to an acidic environment and release somatostatin, which inhibits acid secretion.[48] Nonetheless, gastric mucosa may be exposed to acid for prolonged periods of time, particularly in horses that are extensively meal fed and that do not have the benefit of roughage, which tends to buffer stomach contents.[45,48]

Aside from peptic ulceration induced by combinations of acid and pepsin, research in human medicine has revealed the tremendous importance of *Helicobacter pylori* in inducing ulceration. Infection with this organism has the effect of raising gastric pH because of disruption of gastric glands and also induces an inflammatory reaction that causes damage.[49] However, little evidence to date indicates that this organism is involved in gastric ulcers in horses. In the absence of a known role for infectious agents in gastric ulceration in animals, ulceration likely develops from injurious factors similar to those found in the proximal stomach, including gastric acid and bile. However, some factors that are important to induction of squamous epithelial ulceration may not be important in development of proper gastric mucosal ulceration. For example, feed deprivation and intensive training reproducibly induce squamous epithelial ulceration in horses but have little effect on proper gastric mucosa in horses.[50] Gastric acid likely plays a key role, whereas other factors such as nonsteroidal antiinflammatory drugs (NSAIDs) serve to reduce gastric defense mechanisms. In particular, inhibition of prostaglandin production reduces mucus and bicarbonate secretion while also reducing gastric

mucosal blood flow.[51] Some of the NSAIDs also have a topical irritant effect, although this appears to be of minor significance because the route of administration (oral or parenteral) seems to have little influence on development of ulceration.[52]

The source of prostaglandins responsible for gastric protection originally was assumed to be cyclooxygenase 1 (COX-1), because this isoform is expressed constitutively in gastric mucosa, whereas COX-2 is not expressed in the stomach unless induced by inflammatory mediators. However, mice in which the COX-1 gene has been knocked out fail to develop spontaneous gastric lesions,[53] possibly because of compensatory increases in prostaglandin production by COX-2.[54] This concept agrees with recent data indicating that inhibition of both COX isoforms is required to induce gastric ulceration.[55] From a clinical perspective this data indicate that drugs selective for COX-1 or COX-2 may be less ulcerogenic in the horse. Because COX-2 elaborates prostaglandins induced by inflammatory stimuli, selective inhibitors of COX-2 may be particularly useful because of their ability to serve as antiinflammatory agents that are less ulcerogenic.[56] 804

805

13.5.4 Intestinal Ischemia-Reperfusion Injury

The most notable cause of intestinal mucosal injury in horses, particularly those suffering from colic, is ischemia. Initially, that a reduction in gastrointestinal blood supply leads to mucosal injury seems intuitive. However, the anatomy of the gastrointestinal tract and the differing structure of the intestinal mucosa at various anatomic locations have a significant influence on the extent of mucosal injury. Furthermore, ischemic injury may be induced by several different mechanisms, including occlusion of arterial supply by a thrombus, strangulation of intestinal vasculature, and generalized reduction in blood flow associated with various shock states. In addition, a number of seemingly distinct mechanisms of intestinal injury, such as intestinal distention, also trigger mucosal injury via an ischemic mechanism. Finally, reperfusion injury also may influence the extent of mucosal injury following an ischemic episode and has been pro posed as a potential site of therapeutic intervention.[57,58] Thus understanding the mechanisms of ischemia-reperfusion injury is critical to developing an understanding of the severity of various clinical conditions and beginning to formulate a therapeutic approach to diseases characterized by this devastating form of injury.

13.5.4.1 REGULATION OF INTESTINAL BLOOD FLOW

The intestinal circulation is capable of closely regulating blood flow during periods of low systemic perfusion pressure.[59,60] In particular, local regulation of resistance vessels within the microvasculature is particularly prominent, whereby metabolic end products of adenosine triphosphate (ATP) result in continued dilation of resistance vessels despite reductions in systemic arterial pressure. Dilation results in continued perfusion of gastrointestinal tissues during the early stages of shock, while other organs such as skeletal muscle undergo massive shunting of blood resulting from increased constriction of resistance vessels. The reasons for these differences in regulation are not entirely clear but may relate to the high level of energy required to fuel the intestinal mucosa and the serious systemic effects of breaches in the mucosal barrier. However, as blood flow falls below a critical level, regulatory systems are no longer effective and oxygen uptake by the gastrointestinal tissue decreases, culminating in tissue damage.[59]

The tip of the villus is the most susceptible region affected by hypoxia in the equine small intestine, largely because of the countercurrent exchange mechanism of blood flow in the small intestinal villus.[59] This countercurrent exchange mechanism is attributable to the vascular architecture, which consists of a central arteriole that courses up the core of the villus, arborizes at the tip, and is drained by venules coursing down the

periphery of the villus.[61] As oxygenated blood flows into the central arteriole, oxygen tends to diffuse across to the adjacent venules, which flow in the opposite direction. This series of events takes place along the length of the villus, resulting in a tip of the villus that is hypoxic even under normal conditions. Furthermore, reduced blood flow as occurs in shock exacerbates the countercurrent exchange of oxygen, and the tip becomes absolutely hypoxic.[59] This mechanism might explain why the small intestinal mucosa is more susceptible to ischemic injury, compared with the colon, which has no villi. For example, the duration required to produce severe morphologic damage to the equine colon is approximately 25% longer than in the small intestine.[62]

13.5.4.2 ISCHEMIC EPITHELIAL INJURY

Intestinal mucosal epithelium is susceptible to hypoxia because of the high level of energy required to fuel the Na^+/K^+-ATPase that directly or indirectly regulates ion and nutrient flux. The first biochemical event to occur during hypoxia is a loss of oxidative phosphorylation. The resulting diminished ATP concentration causes failure of the energy-dependent Na^+/K^+-ATPase resulting in accumulation of sodium, and subsequently intracellular water. The pH of the cytosol drops as lactic acid and inorganic phosphates accumulate from anaerobic glycolysis. The falling pH damages cell membranes, including lysosomal membranes, resulting in the release and activation of lysosomal enzymes into the cytosol, further damaging cellular membranes. Damage to the cell membrane allows the accumulation of high concentrations of calcium in the cytosol, which activates calcium-dependent degradative enzymes.[63] These events result in cytoplasmic blebbing of the basal membrane with subsequent detachment of cells from the underlying basement membrane.

Recent studies on epithelial injury during ischemia suggest that most epithelial cells undergo programmed cell death (apoptosis) during ischemia and reperfusion rather than necrosis, allowing retention of reusable components of irreversibly injured cells.[64] In one study, 80% of detached epithelium during small intestinal ischemia and reperfusion underwent apoptosis.[65] Although the most obvious result of apoptosis is loss of surface epithelium, a number of cells on the lower portion of the villus (in the small intestine) and cells within the crypts also may undergo apoptosis that only may become evident up to 24 hours following reperfusion of ischemic tissue.[66]

Morphologic changes observed in ischemic-injured small intestinal mucosa follow a similar sequence regardless of whether ischemia alone or ischemia and reperfusion induce injury (Table 13.5-1).[67] Initially, 805
epithelium separates from the underlying basement membrane, forming a fluid-filled space termed 806
Grüenhagen's space (Figure 13.5-1). The mechanism of fluid accumulation in this space is not understood entirely but may result from continued epithelial absorption of NaCl and water before it has detached fully from neighboring epithelial cells. This fluid accumulation likely exacerbates epithelial separation from the basement membrane. Subsequently, epithelium progressively sloughs from the tip of the villus toward the crypts, which are the last component of the intestinal mucosa to become injured.[68–70] Injury of crypts likely relates to the vascular architecture, because crypts receive a blood supply separate from the vasculature involved in the villous countercurrent exchange mechanism. The early morphologic changes observed in the equine large colon during ischemia are different from those described in the equine small intestine because of the lack of intestinal villi. However, as might be expected, the more superficially located surface cells are sloughed before those in crypts.[62,71] The orderly progression of tissue injury has been used by one group of investigators to predict accurately the survival of horses with large colon volvulus. The researchers took biopsies from the pelvic flexure, which has been shown previously to reflect mucosal changes along the length of the colon accurately,[72] and examined them histologically for the width of the crypts and intercrypt

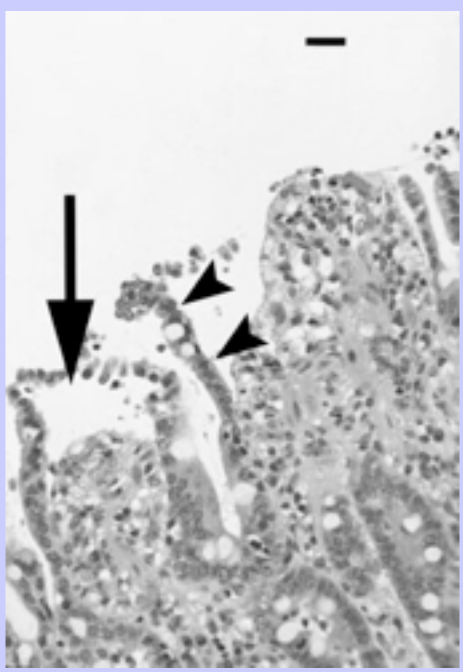
interstitial space. They expressed the latter measurements as a ratio of interstitium to crypt width (I:C) and defined nonviable colon as that which has greater than 60% loss of crypt and an I:C ratio greater than 3. Using this methodology, researchers correctly predicted survival in 94% of horses.[73]

TABLE 13.5-1 Grading System for Ischemia-Reperfusion Injury in Small Intestinal Mucosa

GRADE	DESCRIPTION
1	Separation of epithelium at the tip of the villus, creating a small space between epithelium and basement membrane called Grüenhagen's space
2	Loss of epithelium from the tip of the villus
3	Loss of epithelium from the upper third of the villus
4	Complete loss of villus epithelium
5	Injury or loss of epithelium within the crypt in addition to complete loss of villus epithelium

Modified from Chiu CJ, McArdle AH, Brown R et al: Intestinal mucosal lesion in low-flow states. 1. A morphological, hemodynamic, and metabolic reappraisal, *Arch Surg* 101:478–483, 1970.

Figure 13.5-1 Histologic appearance of Grüenhagen's space in ischemic injured ileal mucosa. Separation of epithelium at the tip of the villous from its basement membrane creates a space *(arrows)*. Epithelium subsequently sloughs into the lumen *(arrowheads)*. 1-cm bar = 100 μm.



13.5.4.3
STRANGULATING OBSTRUCTION

Because of the dramatic decline in *Strongylus vulgaris*–induced colic, which was associated frequently with infarction of intestinal arterial blood supply,[74] most ischemic lesions are associated with strangulating obstruction. Therefore considering mechanisms of ischemic injury in horses with naturally occurring strangulating lesions is important. The majority of experimental work has assessed complete ischemia (complete occlusion of the arterial blood supply)[62] or low-flow ischemia (during which arterial blood flow is reduced).[75,76] However, during intestinal strangulation, a disparity between the degree of occlusion of the veins and arteries occurs whereby veins are occluded before arteries because of differences in compliance of vascular walls. Thus strangulating lesions are typically hemorrhagic (hemorrhagic strangulating obstruction) as the arteries continue to supply blood to tissues that have little or no venous drainage. The result is ischemic injury, as previously outlined, but also a tremendous congestion of the tissues. Such hemorrhagic congestion has two opposing effects: it disrupts tissue architecture, including the mucosa and its epithelium, and continues to provide oxygenated blood to the tissues during much of the ischemic episode. In contrast, when strangulation results in sudden cessation of arterial blood flow (ischemic strangulating obstruction), tissues appear pale, and the mucosa rapidly degenerates because of a complete lack of oxygenated blood.[70] From a clinical standpoint, this makes assessing the degree of mucosal injury in horses with strangulating injuries 806
difficult because intestine that may look nonviable (dark red) may in fact have less mucosal injury than that of 807
ischemic strangulated intestine.[77]

An additional consideration in clinical strangulating obstruction is the degree of ischemia that intestinal distention may induce. For example, experimental distention (18 cm of H_2O for 2 hours) and decompression (2 hours) of jejunum resulted in a significant increase in microvascular permeability and a significant decrease in tissue oxygenation similar to that which would be expected with low-flow ischemia.[78,79] In particular, microscopic evaluation of vasculature revealed capillary endothelial cell damage and local edema formation.[80] This data suggest that distended intestine proximal to an obstruction may undergo mucosal injury despite its normal appearance. Indeed, in one study, intraluminal pressures greater than 15 cm H_2O in naturally occurring cases of colic correlated with a poor prognosis for survival.[81]

13.5.4.4
REPERFUSION INJURY

Although that reperfusion of ischemic tissues results in exacerbation of mucosal injury recently has been taken for granted, one should remember that mechanisms underlying intestinal reperfusion injury have been defined largely in laboratory animals under specific conditions.[82–86] However, studies on reperfusion injury in horses have had some conflicting results.[68,76,87] The conflict may be attributable to the way in which the studies have been performed. In particular, the type of ischemia used in most laboratory animal studies has been low-flow ischemia (in which the blood flow typically is reduced to 20% of baseline flow), whereas studies in horses have used a number of different ischemic models, including various types of strangulating obstruction. Although strangulating obstruction is of great clinical relevance, this type of ischemic insult is less likely to develop reperfusion injury.[68,88,89] Conversely, low-flow ischemia appears to prime tissues for subsequent injury once the tissue is reperfused, and considerable evidence supports the presence of reperfusion injury in horses following low-flow ischemia.[75,76,80,90] Nonetheless, low-flow ischemia may not be a common clinical entity.

TABLE 13.5-2 Comparison of Mean Levels of Xanthine Oxidase/Xanthine Dehydrogenase and Myeloperoxidase (as an Indication of Granulocyte Numbers) in the Small Intestine of Various Species

SPECIES	INTESTINAL SEGMENT	TOTAL XO/XDH (mU/gTISSUE)	MYELOPEROXIDASE (U/gTISSUE)	REFERENCE
Cat (adult)	Jejunum	80	12	86, 143
	Ileum	NR	NR

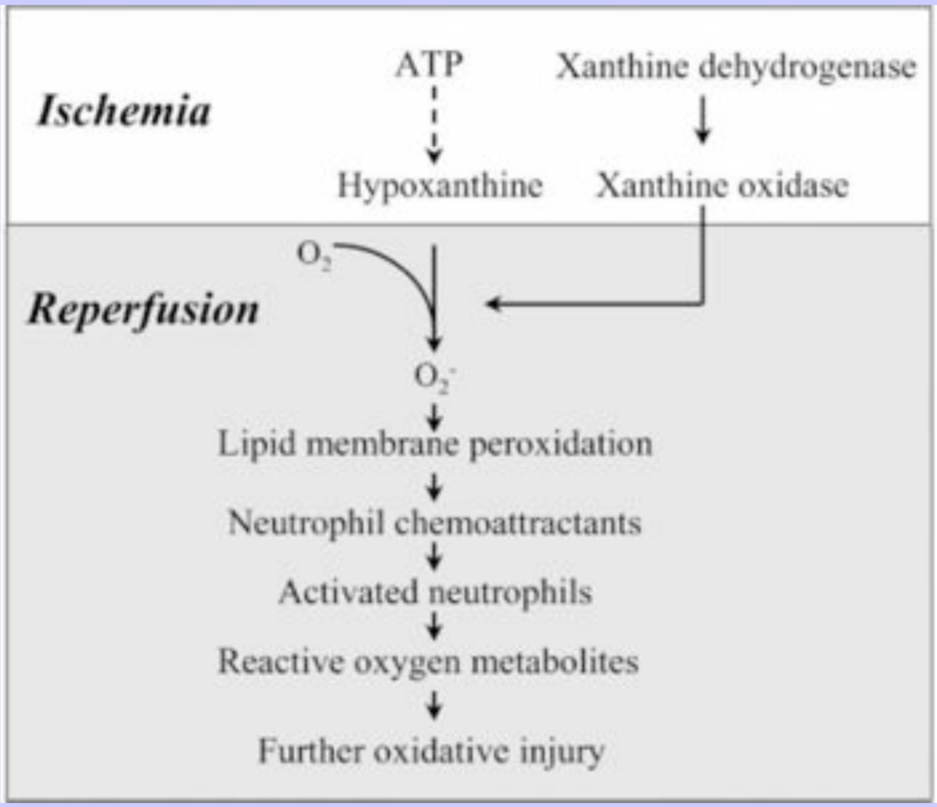
† Value in parentheses for the foal.

In addition to the type of ischemia, other factors are involved in priming tissues for reperfusion injury, including species and anatomic-specific variation in oxidant enzyme and neutrophil levels (Table 13.5-2). For example, the foal appears to have low levels of small intestinal xanthine oxidase, an enzyme that has been shown to play a critical role in triggering reperfusion injury in laboratory animals,[84,85,91] whereas adult levels are much greater, particularly in the proximal small intestine.[92] In addition, horses appear to have low numbers of resident neutrophils in the intestinal mucosa,[93] and this population of neutrophils (rather than those recruited from the circulation) appears to be most critical for induction of reperfusion injury.[86] However, studies demonstrating reperfusion injury in the equine colon following low-flow ischemia have shown significant accumulation of neutrophils within the mucosa.[75] Therefore a complete understanding of mechanisms of neutrophilic infiltration and the mechanisms whereby they damage tissue requires further study.

Reperfusion injury is initiated during ischemia when the enzyme xanthine dehydrogenase is converted to xanthine oxidase and when its substrate, hypoxanthine, accumulates simultaneously because of ATP use (Figure 13.5-2).[57,94] However, little xanthine oxidase activity occurs during ischemia, because oxygen is 807
required as an electron acceptor. During reperfusion, xanthine oxidase rapidly degrades hypoxanthine in the 808
presence of oxygen, producing the superoxide radical as a by-product.[57] The superoxide radical contributes to oxidative tissue damage and, most importantly, activates neutrophil chemoattractants.[84,85] Thus inhibition of xanthine oxidase in feline studies of intestinal ischemia-reperfusion injury prevents infiltration of neutrophils and subsequent mucosal injury.[83,84] However, inhibition of xanthine oxidase has had no effect on ischemia-

reperfusion injury in equine small intestine[87] and colon,[95] suggesting that reperfusion injury is simply a continuation of injury initiated during ischemia, as suggested in some equine studies,[63] or that the classic reperfusion injury pathway is activated by alternate sources of reactive oxygen metabolites. The latter has been suggested by studies in feline models of ischemia-reperfusion injury in which the source of a significant proportion of reactive oxygen metabolites is unknown and is independent of xanthine oxidase and neutrophils.[83]

Figure 13.5-2 Intestinal reperfusion injury cascade. Reperfusion injury is initiated by elaboration of superoxide by metabolism of hypoxanthine by xanthine oxidase and subsequent infiltration of neutrophils.



A veterinary review of the pathogenesis of intestinal reperfusion injury in the horse suggested the concept of a therapeutic window wherein treatment of reperfusion injury would be beneficial.[57] The basis of this concept is that certain conditions exist under which ischemic injury is minimal and that tissues are damaged severely during reperfusion.[88] Thus under conditions of low-flow ischemia, little injury is demonstrated during 3 hours of ischemia, but remarkable injury occurs during 1 hour of reperfusion.[83–85] However, a therapeutic window may not exist under conditions of strangulating obstruction in which severe injury occurs during ischemia and minimal injury occurs during reperfusion.[96] This in turn greatly reduces clinicians' ability to ameliorate ischemia-reperfusion injury with treatments such as antioxidants at the time of reperfusion.

13.5.5 Mechanisms of Gastrointestinal Mucosal Repair

13.5.5.1 GASTRIC REPARATIVE MECHANISMS

Mechanisms of gastric repair depend greatly on the extent of injury. For instance, superficial erosions can be covered rapidly by migration of epithelium adjacent to the wound; a process termed *epithelial restitution*. However, ulceration (full-thickness disruption of mucosa and penetration of the muscularis mucosa) requires repair of submucosal vasculature and extracellular matrix. The formation of granulation tissue initiates repair and supplies connective tissue elements and microvasculature necessary for mucosal reconstruction. Connective tissue elements include proliferating fibroblasts that accompany newly produced capillaries that form from proliferating endothelium. Recent studies indicate that nitric oxide is critical to both processes,[40,97] which likely explains the reparative properties of nitric oxide in the stomach.[98]

Once an adequate granulation bed has formed, newly proliferated epithelium at the edge of the wound begins to migrate across the wound. In addition, gastric glands at the base of the ulcer begin to bud and migrate across the granulation bed in a tubular fashion.[99] Repairing epithelium expresses epidermal growth factor, which appears to facilitate these processes.[100] In addition, a mucoid cap facilitates these events and retains reparative factors and serum adjacent to the wound bed.[51] Once the ulcer crater has been filled with granulation tissue and the wound has been reepithelialized, the subepithelial tissue remodels by altering the type and amount of collagen. Despite the remodeling process, ulcers tend to recur at sites of previous ulceration, and the concern is that this remodeling can result in excessive deposition of collagen and fibrosis.[26]

13.5.5.2 INTESTINAL REPARATIVE MECHANISMS

Reparative mechanisms are similar in the intestine, except that in the small intestine, mucosal villi contribute to mucosal repair. Once intestinal epithelium is disrupted, two events occur almost immediately to reduce the size of the denuded portion of the villus: contraction of the villus and epithelial restitution (Figure 13.5-3). For example, in porcine ileum subjected to 2 hours of ischemia, villi were 60% of their former height and 50% of the denuded villous surface area was covered in flattened epithelium within 6 hours.[42] Enteric nerves appear to regulate villous contraction, because inhibition of enteric nerve conduction prevents villous shortening 808
following injury. The contractile component of the villus is a network of myofibroblasts distributed 809
throughout the lamina propria of the villus and along the central lacteal. Inhibition of villous contraction results in retarded epithelial repair because of the larger denuded surface that remains to be covered by migrating epithelium compared with similarly injured villi that have contracted.[43] PGE_2 also has been implicated in regulating villous contraction, because application of PGE_2 resulted in villous contraction when perfused through normal rat ileum.[101] As villi contract, assuming the basement membrane is intact, epithelium from the margins of the wound migrates centripetally to resurface toward the tip of the villus.[43] The process of restitution is similar in denuded colonic mucosa, except that it may proceed more rapidly because of the lack of villi.[41] Epithelial restitution is solely a migratory event that does not depend on provision of new enterocytes by proliferation. Cellular migration is initiated by extension of cellular lamellipodia that receive signals from the basement membrane via integrins. Intracellular signaling converges on the actin cytoskeleton, which is responsible for movement of lamellipodia. Specific components of the basement membrane appear to be critical to the migratory process. For example, application of antibodies to collagen types III and IV, which

are important components of intestinal mucosal basement membrane, impeded epithelial restitution.[102,103] Other elements of the basement membrane, including proteoglycans, hyaluronic acid and noncollagenous proteins such as fibronectin and laminin also may provide important signals.[104] These subepithelial matrix components that facilitate restitution may form the basis for clinical treatments designed to speed up the repair process, analogous to administration of matrix components to horses with articular cartilage damage.

Although epithelial restitution results in gross closure of previously denuded regions of gastrointestinal mucosa, closure of interepithelial spaces ultimately is required to restore normal epithelial barrier resistance. Because the tight junction is principally responsible for regulating the permeability of the interepithelial space, repair and closure of this structure likely is critical to restore intestinal barrier function. Recent research indicates that prostaglandins play a vital role in recovery of tight junction resistance,[105] indicating that administration of nonselective COX inhibitors to horses with colic, particularly those recovering from strangulating obstruction, may be deleterious. Therefore judicious use of NSAIDs is appropriate until more selective drugs that allow continued production of reparative prostaglandins are available for use in horse.[56]

After restoration of the epithelial barrier, the epithelium must reestablish normal mucosal architecture to allow normal gut absorptive and digestive function. In porcine ileum subjected to 2 hours of ischemia, the epithelial barrier was restored within 18 hours, but villi were contracted and covered in epithelium with a squamous appearance. Restoration of normal villous architecture required another 4 days.[42] Newly proliferated crypt epithelium replaces the flattened villous epithelium that characterizes restitution. Under normal circumstances the dividing stem cells, of which the base of each mucosal crypt has approximately four, form new enterocytes. Newly divided enterocytes migrate from the crypt onto the villus.[106] During migration, enterocytes differentiate and acquire specific absorptive and digestive functions. Fully differentiated enterocytes reside on the upper third of the villus for 2 to 3 days and then are sloughed into the intestinal lumen.[107] This process accelerates during mucosal repair and requires increased proliferative rates. A variety of locally available gut-derived factors, including luminal nutrients, polyamines, and growth factors, may stimulate increased proliferation within 12 to 18 hours.[42] The return of the normal leaflike shape of the villus occurs following the appearance of normal columnar epithelium.

13.5.6 Mediators of Repair

13.5.6.1 PROSTAGLANDINS

Although prostaglandins have been implicated in mucosal cytoprotective function, few studies have assessed their importance in mucosal repair. One study implicated prostaglandins in growth factor-stimulated restitution,[108] but a more prominent role of prostaglandins in mucosal repair is their ability to close interepithelial tight junctions.[105,109,110] For instance, ischemic-injured small intestine rapidly recovers barrier function (as measured in vitro as transepithelial resistance) in the presence of PGI_2 and PGE_2, despite the fact that these prostanoids had little effect on villous contraction and epithelial restitution. However, electron microscopic examination of tissues reveals dilation of tight junctions in tissues treated with NSAIDs,[110] whereas those additionally treated with prostaglandins have closely apposed tight junctions (Figures 13.5-3 and 13.5-4). Prostaglandins stimulate closure of tight junctions via the second messengers cyclic adenosine monophosphate and Ca^{2+},[105] which interestingly were among the first mediators found to modulate tight junction permeability.[111,112] Such tight junction closure is of importance to patients with intestinal injury that are treated with NSAIDs, because reduced prostaglandin levels may result in increased intestinal permeability.

For example, in a study on ischemic-injured porcine ileum, treatment with the NSAID indomethacin resulted in a significant increase in intestinal permeability to inulin and lipopolysaccharide compared with tissues that were treated additionally with PGI_2 and PGE_2.[105]

809

810

Figure 13.5-3 Histologic appearance of repairing intestinal mucosa 6 hours following a 2-hour ischemic episode. Blunting of the villi, attributable to villous contraction, and evidence of epithelial restitution *(arrows)* are notable. 1-cm bar = 100 μm.

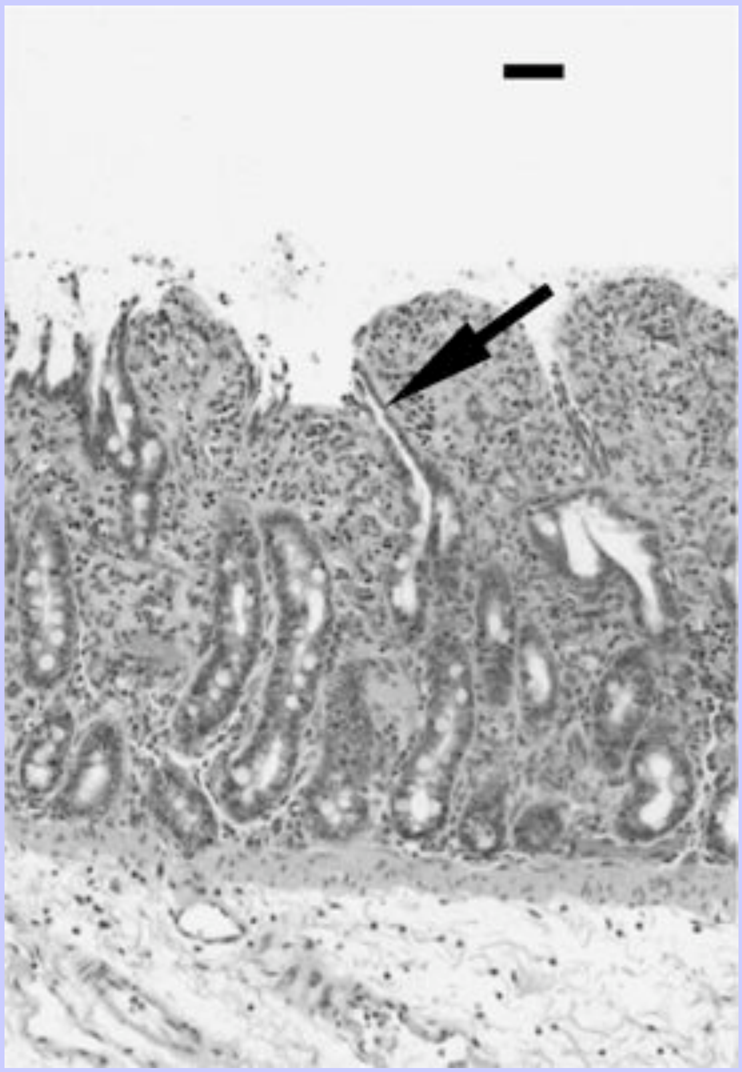


Figure 13.5-4 Ultrastructural appearance of repairing ischemic-injured mucosa. **A,** Restituting epithelium 2 hours following a 1-hour ischemic episode in the presence of the nonselective cyclooxygenase inhibitor indomethacin. Dilation of the interepithelial space and the apical tight junction *(arrows)* correlates with a leaky intestinal barrier, **B,** Similar restituting epithelium had been treated additionally with prostaglandins E_2 and I_2. The close apposition of the tight junction *(arrows)* and the interepithelial space correlate with normalization of intestinal barrier function. 1-cm bar = 6 μm.

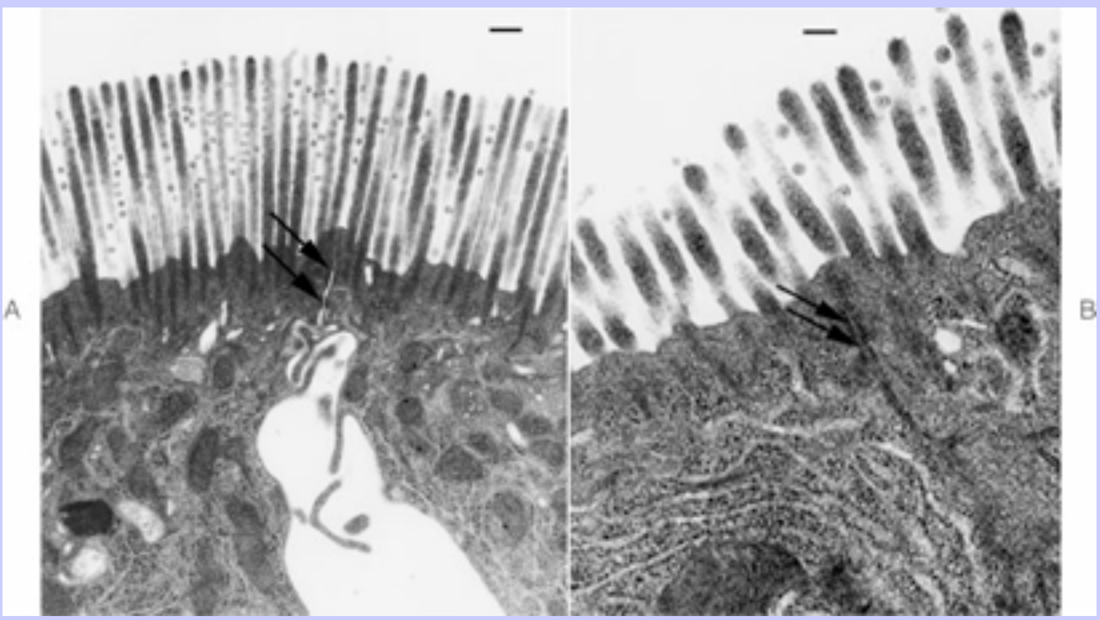

13.5.6.2 POLYAMINES

The process of restitution absolutely depends on a group of compounds called polyamines.[113,114] The rate-limiting enzyme in the formation of the polyamines spermine, spermidine, and putrescine is ornithine decarboxylase. In rats with stress-induced duodenal ulcers, systemic administration of the ornithine decarboxylase inhibitor α-difluoromethylornithine significantly reduced polyamine levels and greatly reduced epithelial restitution. Furthermore, intragastric treatment of these same rats with putrescine, spermidine, and spermine prevented the delayed mucosal repair induced by α-difluoromethylornithine.[113] Interestingly, gastric tissue levels of ornithine decarboxylase increased in rats with stress-induced gastric ulcers, suggesting that tissue injury enhances polyamine production, which may contribute to the normal rapid rate of epithelial restitution.[115]

The mechanisms whereby polyamines stimulate epithelial restitution are not clear. McCormack, Wang, Viar, et al. hypothesized that polyamines increase transglutaminase activity, an enzyme that catalyzes the cross-linking of cytoskeletal and basement membrane proteins.[116] Further investigation of the role of polyamines in IEC-6 cell migration showed that depletion of polyamines resulted in disruption of the cytoskeleton and 810
reduced the physical extension of lamellipodia.[117] More recent studies have clarified this pathway. In 811
particular, polyamines have been shown to regulate cytoskeletal cellular migration via activation of the small guanosine triphosphatase-Rho-A by elevating intracellular Ca^{2+} levels. These elevations in Ca^{2+} result from polyamine regulation of expression of voltage-gated K^+ channels and altered membrane electric potential.[118]

Polyamines also play a role in the normal physiologic regulation of crypt cell proliferation and differentiation.[119,120] Polyamines are produced by fully differentiated enterocytes at the tip of the villus and may reach the crypt within sloughed luminal epithelium or via local villous circulation.[121] Following intestinal injury, polyamines appear to stimulate enhanced proliferation by increasing the expression of protooncogenes, which control the cell cycle.[122] The mechanism whereby polyamines influence gene expression likely relates to the cationic nature of these compounds, which may influence the tertiary structure of negatively charged DNA and RNA.[113]

13.5.7 GROWTH FACTORS

Locally produced growth factors—including epidermal growth factor (EGF), transforming growth factor α (TGF-α), TGF-β, and hepatocyte growth factor—have the ability to modulate mucosal recovery. The most important of these growth factors in early mucosal repair events is TGF-β, which is a potent stimulus of epithelial restitution and modulator of the extracellular matrix.[26] Neutralization of TGF-β retards epithelial migration in vitro, and TGF-β apparently may serve as a point of convergence for mediators of restitution, because neutralizing TGF-β also inhibits the effects of other peptides. However, TGF-β paradoxically inhibits epithelial proliferation, thereby reducing the supply of new enterocytes for mucosal repair. Conversely, EGF, produced by the salivary glands and duodenal Brunner's glands, and the related TGF-α, produced by small intestinal enterocytes, are potent stimulants of enterocyte proliferation. These growth factors share approximately 30% of their amino acid structure, bind to the same receptor on the basolateral surface of enterocytes, and are not related to TGF-β.[123] The physiologic role of EGF is difficult to discern because it is present in the intestinal lumen, with no apparent access to its basally located receptor. However, EGF has been proposed to act as a "surveillance agent" that gains access to its receptor during epithelial injury (when the EGF receptor likely would be exposed) to stimulate proliferation.[124] TGF-α presumably has a similar role, but it is present in greater concentrations in the small intestine because it is produced by differentiated villous enterocytes. The mature peptide is cleaved from the extracellular component of the transmembrane TGF-α precursor and released into the lumen.[123]

13.5.7.1 TREFOIL PEPTIDES

Another group of proreparative peptides produced within the gastrointestinal tract are the trefoil peptides. Under physiologic conditions, trefoil peptides are secreted by mucus-producing cells at distinct anatomic sites. For example, gastric epithelium produces the trefoil peptide pS2, whereas the small and large intestine mucosa produce intestinal trefoil peptide.[125] However, any of the trefoil peptides may be upregulated within repairing epithelium regardless of anatomic site.[26,126] In addition, trefoil peptides have the ability to induce their own

expression, amplifying the level of these reparative factors at sites of mucosal repair.[127] Trefoil peptides are the most potent stimulants of epithelial migration in vitro, and their effects are independent of growth factors, including TGF-β.[128] However, recent evidence suggests that EGF receptor activation is required for induction of pS2 and another of the trefoil peptides, termed *spasmolytic peptide,* in gastric epithelium in vitro. The importance of trefoil peptides to the mucosal repair response in vivo is illustrated by gene knockout studies, in which mice deficient in intestinal trefoil factor have greatly reduced ability to repair intestinal injury.[129] In fact, detergent-induced mucosal injury was lethal because of a lack of restitution compared with wild-type mice that fully recovered from similar mucosal injury. The fact that administration of intestinal trefoil factor restored restitution has important therapeutic implications. The mechanism whereby trefoil peptides stimulate epithelial migration is yet to be characterized fully but appears to involve translocation of the adherens junction protein E-cadherin, thereby allowing cells to become untethered from neighboring cells.[26]

13.5.7.2

INTESTINAL NUTRIENTS

The principal metabolic fuel of enterocytes is glutamine and of colonocytes, butyrate. However, recent studies suggest that glutamine and butyrate have more specific proliferative actions aside from their role as nutrients. For example, in the piglet IPEC-J2 enterocyte cell line, glutamine enhanced gene transcription by increasing mitogen-activated protein kinase activity.[130,131] Similarly, butyrate stimulated mucosal growth following colonic infusion in the rat.[132] Because of such growth-promoting actions, glutamine was shown to prevent intestinal mucosal atrophy and dysfunction that accompanies starvation[133,134] and long-term total parental nutrition.[135,136] Additionally, glutamine improves function of transplanted small intestine[137,138] and protects intestinal mucosa from injury if administered before chemotherapy[139] and radiation therapy.[140,141] Intestinal 811
nutrients also may synergize with other proliferative agents. For example, administration of glutamine and 812
TGF-α to porcine ileum that had been subjected to 2 hours of ischemia resulted in a synergistic increase in mitogen-activated protein kinase activity, enterocyte proliferation, and villous surface area.[42] Although concern has arisen that such early return to normal surface area may result in dysfunctional mucosal digestive and absorptive function because of resurfacing denuded mucosa with immature epithelium, nutrients and growth factors also appear to promote early differentiation. In the case of glutamine and TGF-α restoration of postischemic small intestine, rapid recovery of digestive enzymes also was documented.[142]

13.6

13.6—Gastrointestinal Ileus

Guy D. Lester

Effective gastrointestinal motility involves a complex interaction between the enteric nervous system, muscular wall, and luminal contents. Additional factors that influence the net transit of digesta include gravity, the volume and viscosity of the contents, and pressure gradients created by simultaneous contraction and relaxation of adjacent segments of bowel. Casual use of the term *intestinal motility* in veterinary medicine often underestimates the complexity of the processes involved in the transit of intestinal contents. This is particularly true when the term is used to describe the frequency and or intensity of intestinal sounds, or borborygmi. The existence of borborygmi does not always equate with progressive movement of intestinal contents.

Disruption to normal motility occurs commonly in horses for a variety of reasons. Examples of diseases in which altered motility may be present include gastroduodenal ulceration, intraluminal obstruction or impaction, excessive wall distention, strangulating obstructions, peritonitis, and inflammatory bowel diseases such as duodenitis proximal jejunits or colitis. Ineffective intestinal motility is also a feature of several neonatal diseases, including prematurity, systemic sepsis, and perinatal asphyxia. Certain parasitic infections, electrolyte derangements, and endotoxemia can modify digesta transit in horses of all ages. General anesthesia and specific sedatives, such as xylazine, romifidine, or detomidine, also disturb motility.

13.6.1

Postoperative Ileus

The inhibition of propulsive bowel activity usually is referred to as ileus. Ileus is ascribed most frequently to the condition that occurs after laparotomy and is termed *simple* or *uncomplicated postoperative ileus* (POI). The 815

816 term *complicated* or *paralytic ileus* describes intestinal motility disturbed for longer periods after surgery. POI in horses is associated most commonly with surgery of the small intestine, particularly after resection and anastomosis,[1,2] is a common complication of small intestinal surgery, and can have a negative effect on short-term postoperative survival.[3,4] Motility dysfunction likely is present in all horses after laparotomy, but many are affected subclinically and require minimal or no specific intervention. In symptomatic animals, clinical signs are apparent shortly after recovery and include colic, tachycardia, dehydration, decreased borborygmi and fecal output, and sequestration of fluid within the stomach. Rectal examination and ultrasound reveal small intestinal distention with rare or absent wall movement. The severity and duration of intestinal stasis varies, lasting from minutes to days.

13.6.2

Cecal Emptying Defect

A specific motility disorder involving the cecum or ileocecocolic region occurs sporadically in horses.[5–7] The condition most commonly occurs after general anesthesia and extraabdominal surgery, particularly orthopedic and upper airway procedures, and therefore often is categorized as a form of POI. Anecdotally, horses at greatest

risk are young male performance animals. Other cases occur spontaneously, often in animals with painful primary conditions such as uveitis or septic tenosynovitis. The syndrome is frustrating in that clinical signs are often subtle unless cecal perforation has occurred. In horses with a cecal emptying defect after anesthesia, overt signs are usually apparent 3 to 5 days after the procedure. The earliest detectable signs include depression and a reduction in feed intake and fecal output. Ineffective emptying results in overfilling of the cecum with moist contents, which is manifest by signs of mild to moderate colic. If the condition is recognized late or untreated, the cecum may rupture and result in fatal peritonitis.

13.6.3 Physiology

The inherent rhythmicity of electric activity in the intestine is controlled by the interstitial cells of Cajal, specialized cells that are electrically coupled to myocytes via gap junctions.[8] These cells are responsible for generating and propagating slow-wave activity and may be critically involved in a range of motility disorders. The enteric nervous system primarily controls and coordinates intestinal contraction. A combination of central and autonomic innervation influences events, but contraction does not require external neural input. The parasympathetic supply to the gastrointestinal tract is via the vagus and pelvic nerves, and the sympathetic supply is through postganglionic fibers of the cranial and caudal mesenteric plexuses. A complex network of interneurons within each plexus integrates and amplifies neural input; the intensity and frequency of resultant smooth muscle contractions are proportional to the amount of sympathetic and parasympathetic input. Additional binding sites for a number of other endogenous chemicals, including dopamine, motilin, and serotonin exist within the enteric nervous system and on smooth muscle cells.[9] Acetylcholine is the dominant excitatory neurotransmitter in the gastrointestinal tract and exerts its action through muscurinic type 2 receptors on smooth muscle cells. Sympathetic fibers innervating the gastrointestinal tract are adrenergic, postganglionic fibers with cell bodies located in the prevertebral ganglia. Activation of α_2-adrenergic receptors on cholinergic neurons within enteric ganglia inhibits the release of acetylcholine and therefore reduces intestinal contraction.

β_1-, β_2-, and β-atypical receptors are directly inhibitory to the intestinal smooth muscle.[10] Inhibitory nonadrenergic, noncholinergic neurotransmitters include adenosine triphosphate, vasoactive intestinal peptide, and nitric oxide.[11,12] These neurotransmitters are critical for mediating descending inhibition during peristalsis and receptive relaxation. Substance P is a nonadrenergic, noncholinergic neurotransmitter that may be involved in contraction of the large colon.[13,14]

The rate and force of intestinal contractions along the small intestine and large colon of the horse are important determinants of intestinal motility; of even greater importance to the net propulsion of digesta are the cyclical patterns of contractile activity. These patterns are known as the small intestinal and colonic migrating motility (or myoelectric) complexes (MMCs).[15,16] The colonic complex usually originates in the right ventral colon and variably traverses the ascending and descending colons. Many of these complexes are related temporally to a specialized motility event of the ileum, the migrating action potential complex.

13.6.4 Pathophysiology

13.6.4.1 INFLAMMATION

Local inflammation within the intestinal muscularis and inhibitory neural events are important initiators of intestinal ileus.[17,18] Intestinal inflammation not only is important in primary intestinal diseases in horses, such

as duodenitis-proximal jejunitis and colitis but also is induced after simple intestinal handling during laparotomy. Experimental data from other species suggests that handling of the small or large intestine at the time of surgery activates resident macrophages with resultant increased expression of P-selectin and intercellular adhesion molecule 1 on endothelial cells within the vasculature of the muscularis. The 816
upregulation of associated ligands on leukocytes leads to sequential “sticking and rolling,” followed by 817
neutrophil migration into the interstitium. The subsequent release of neutrophil products interferes with cell signaling and results in reduced intensity of smooth muscle contraction. Furthermore, the inflamed intestine fails to contract normally in response to putative prokinetic agents.

Another key factor in the development of intestinal stasis after inflammation is the local overproduction of nitric oxide caused by the upregulation of inducible nitric oxide synthase (iNOS) by resident macrophages. Nitric oxide is a key inhibitory neurotransmitter of the nonadrenergic, noncholinergic system.[12] Nitric oxide synthase inhibition has been a pharmacologic target in the treatment of experimental ileus.

13.6.4.2 DRUGS

The inhibitory effects of α_2-agonists such as xylazine and detomidine on cecal and large colon motility are well described.[19–24] Intravenously administered xylazine inhibits cecal and large colon motility for 20 to 30 minutes without seriously disrupting small intestinal myoelectric activity, and detomidine can reduce large intestinal myoelectric activity for up to 3 hours. The α_2-antagonist yohimbine has a weak but positive effect on cecal emptying in normal ponies, suggesting that normal motility is under constant α_2-adrenergic tone.[24]

Atropine is a postganglionic blocking agent that binds to muscarinic receptors. When administered at 0.04 mg/kg, atropine inhibits individual small intestinal, cecal, and colonic contractions for about 120 minutes but supresses small intestinal and colonic migrating complexes for up to 8 hours.[25]

13.6.4.3 NEURAL REFLEXES

Neural reflexes also may mediate inhibition of motility associated with peritoneal inflammation.[26,27] The afferent segment is composed partly of capsaicin-sensitive visceral afferent C fibers that terminate in the dorsal horn of the spinal cord, where they can activate inhibitory sympathetic fibers or synapse directly on the sympathetic ganglia. Consequently, the efferent limb of the reflex expresses increased sympathetic outflow, primarily mediated through stimulation of α_2-adrenoreceptors, and inhibition of acetylcholine release, which provides the rationale for α_2-blockade in treating ileus. Intraluminal infusion of capsaicin before abdominal surgery ameliorated the severity of POI in experimental rats. This finding highlights the importance of visceral afferent fibers in the development of POI.[28]

13.6.4.4 DISTENTION

Ileus also can occur in association with intestinal obstruction or displacement. Mild to moderate distention of the bowel, such as that occurring in the early stages of an intraluminal obstruction, evokes an increase in local contractile activity.[29,30] Excessive distention results in inhibition of motility within the distended segment of bowel. Intestinal stasis is not always detrimental and under certain conditions may be protective.

13.6.4.5

ENDOTOXINS

Endotoxemia is a clinical feature of many diseases of the equine gastrointestinal tract, and endotoxins independently can exert a negative effect on intestinal motility and transit.[31] A variety of mediators likely are involved, but activation of α_2-adrenoreceptors and production of prostanoids appear to be important, for pretreatment with yohimbine or nonsteroidal antiinflammatory drugs (NSAIDs; phenylbutazone or flunixin), respectively, ameliorates the inhibitory effects of experimental endotoxin infusion.[32,33] Endotoxin infusion induced an inflammatory response in the intestine of rats that mimicked the response induced by handling during laparotomy.[34] The similarity of the responses were highlighted in a recent study that demonstrated that prior exposure of the muscularis to endotoxin protected the intestine from the effects of manipulation.[35]

The pathophysiology of cecal emptying defect is not known. This syndrome may best mimic POI in human beings and generally is considered a large intestinal disorder. An important difference in horses is that laparotomy is a rare predisposing factor, and most cases occur in horses undergoing routine extraabdominal surgical procedures. General anesthesia itself is a potent inhibitor of gastrointestinal motility in horses, but these effects are short-lived and reversible within hours of anesthetic withdrawal.[15] The return of normal motility in horses after experimental ileus was most delayed in the cecum, suggesting that this may be a common site of ileus in horses.[36] A link between routine postoperative medications, such as phenylbutazone and aminoglycoside antibiotics, has been suspected but not established. An inhibitory effect of NSAIDs on large colon contractility has been demonstrated using in vitro techniques.[37] Primary sympathetic overstimulation could be involved, for many of the affected animals are young, male horses or animals with painful diseases.

The duration of surgery influences the development of small intestinal POI, but not cecal emptying dysfunction.[7,38] Technique may have a weak influence on small intestinal POI after jejunojejunostomy. The duration of intestinal ileus was shorter in animals that received a side-to-side stapled anastomosis than those that had a hand sewn end-to-end procedure.[3] The duration of ileus after stapled end-to-end anastomosis was not different from that after either procedure.

Reported risk factors for the development of POI in horses include age (>10 years), small intestinal resection 817
and anastomosis, breed (Arabians had a greatest risk than other breeds), and duration of surgery.[38] 818
Interestingly, performing a pelvic flexure enterotomy and emptying the colon had a protective effect against POI.

13.6.5

Diagnosis

The diagnosis of ileus is based on history and physical examination findings. Important tests include determination of pulse rate and rhythm, auscultation and percussion of the abdomen, rectal palpation, and passage of a nasogastric tube. A complete blood count with fibrinogen estimation and cytologic analysis of peritoneal fluid may improve the accuracy of diagnosis. Affected animals may be colicky because of accumulation of fluid in the upper gastrointestinal tract (classical POI) or cecal contents (cecal emptying defect). Decompression of the stomach is important diagnostically and therapeutically in horses with POI after small intestinal surgery. Failure to relieve pain with gastric decompression could point toward mechanical obstruction, severe inflammation of the intestine, or peritonitis. Most animals with ileus are depressed and have reduced fecal output and intestinal borborygmi. One should interpret intestinal sounds with caution, however, because the

presence of borborygmi does not always equate to progressive intestinal motility and merely may reflect local, nonpropagated contractions.

Rectal palpation findings in cases of persistent POI or duodenitis-proximal jejunitis are usually nonspecific but may reveal dilated, fluid-filled loops of small intestine. The clinician occasionally can palpate roughened peritoneal surfaces if peritonitis is present. One can palpate cecal distention with digesta in horses with advanced cecal dysfunction.

Distinguishing functional ileus from mechanical obstruction is important and can be difficult, but horses with mechanical obstruction typically have sustained high volumes of gastric reflux that vary little over time.

13.6.6 Treatment

The management of intestinal ileus depends on the segment of gastrointestinal tract involved. Therapy for ileus of the proximal gastrointestinal tract involves a combination of gastric decompression, fluid and electrolyte therapy, and antiinflammatory drug therapy. Electrolyte therapy is critical, particularly for maintaining adequate extracellular concentrations of potassium, calcium, and magnesium. Calculation of the volume of fluid to be administered should include maintenance requirements (40 to 60 ml/kg/day) plus an estimate of losses, especially those lost through gastric decompression. One should consider parenteral provision of calories when feed has been withheld for more than 96 hours, particularly after the horse has had surgery. A combination of amino acids and dextrose with or without lipids effectively provides these calories. Hand walking also may provide some benefit to these animals but is not likely to have a direct effect on intestinal motility.

One should avoid drugs that may impair normal intestinal motility, including the anticholinergics such as atropine and opiate receptor agonists such as morphine and meperidine. Butorphanol appears to have little or no adverse effect on small or large intestinal motility.[39,40] One should use α_2-agonists sparingly because of their inhibitory effects on large intestinal motility.

Fluid therapy is the key component in managing cecal emptying defect, usually in combination with lubricants or laxatives, such as mineral oil or magnesium sulfate, and with careful use of antiinflammatory drugs. Horses with primary cecal impaction or impaction caused by an emptying defect frequently require surgery to prevent fatal rupture. The surgical management of these cases is controversial and may include typhlotomy alone, typhlotomy with a bypass procedure such as ileocolic or jejunocolic anastomosis, or a bypass without typhlotomy.[41] Most horses that undergo simple typhlotomy have an uneventful recovery,[42] although a small number experience impaction again and require a second laparotomy.

Experimental and anecdotal evidence provides a strong rationale for using antiinflammatory drugs to prevent and treat gastrointestinal ileus, particularly in animals that may have endotoxemia.[43] Flunixin meglumine is used widely in equine practice as an analgesic and antiinflammatory agent, and it ameliorates many of the adverse systemic effects of endotoxin, particularly those on the cardiovascular system. A potential negative effect of NSAIDs on large intestinal contractility has been suggested.

Broad-spectrum antimicrobials are indicated when one suspects sepsis or for the compromised immune system, as in cases of moderate to severe endotoxemia. Theoretical concerns have been raised regarding the use of aminoglycoside antibiotics in animals with ileus. High concentrations of aminoglycoside antimicrobials inhibited intestinal contractions in exposed sections of intestine in vitro, but this inhibitory effect is unlikely to occur at clinically relevant doses.[44]

Motility-enhancing drugs have been advocated to treat gastrointestinal ileus. Unfortunately, information directly pertinent to horses is limited and must be extrapolated cautiously from that of other species because of the differences in intestinal anatomy and physiology. Prokinetic drugs potentially can shorten the length of hospitalization, thereby reducing the cost of treatment and the number of potential complications such as weight loss, thrombophlebitis, and laminitis. Experimental evidence indicates that prokinetic drugs can minimize the 818

819 development of postoperative abdominal adhesions.[45] Most prokinetic drugs require a healthy gut wall to enhance intestinal contraction. Therefore one should not assume that many of these drugs would be effective in the presence of an inflammatory injury such as that which can occur after intestinal manipulation at surgery or that associated with duodenitis-proximal jejunitis.

Bethanechol is a parasympathomimetic agent that acts at the level of the myenteric plexus and directly on intestinal smooth cells through muscarinic receptors. Bethanechol is a synthetic ester of acetylcholine and is not degraded by anticholinesterase. Bethanechol has cholinergic side effects, including abdominal discomfort, sweating, and salivation, although these are minimal when the drug is administered at 0.025 mg/kg body mass subcutaneously or orally. Bethanechol has efficacy in diseases that involve abnormal gastric emptying and delayed small intestinal transit and has been shown to increase gastric contractility and hasten the emptying of liquid and solid phase markers from the stomach of normal horses.[46–47] Bethanechol also increases the strength and duration of wall contractions in the cecum and right ventral colon and consequently speeds up cecal emptying. Neostigmine increases receptor levels of acetylcholine by inhibiting cholinesterase. The drug (0.022 to 0.025 mg/kg intravenously) promotes cecal and colonic contractile activity and hastens the emptying of radiolabeled markers from the cecum.[24] Neostigmine has been used to manage small intestinal ileus, but it significantly delayed the emptying of 6-mm beads from the stomach of normal adult horses.[48]

Metoclopramide acts principally as a 5-hydroxytryptamine 4-receptor (5HT-4) agonist and 5HT-3–receptor antagonist. In contrast to newer generation benzamides, metoclopramide is also an antagonist at dopamine 1 (DA_1) and 2 (DA_2) receptors. Antagonism of prejunctional DA_2 receptors facilitates acetylcholine release and smooth muscle contraction. Metoclopramide crosses the blood-brain barrier, where its antagonist properties on central DA_2 receptors can result in extrapyramidal signs, including seizure. These signs were responsible for poor acceptance of the drug in equine practice. Most investigators have failed to demonstrate significant effects of metoclopramide in experimental animals, but constant intravenous infusion (0.04 mg/kg/hr) in a population of postoperative horses significantly decreased the volume and duration of gastric reflux over control and intermittent drug infusion groups.[49] Infusion was well tolerated and appeared to be superior to intermittent infusion or no treatment at all.

Cisapride is a second-generation benzamide that acts as a 5HT-4 agonist and 5HT-3 receptor antagonist but is without antidopaminergic action. Stimulation of 5HT-4 receptors within the enteric nervous system enhances release of acetylcholine from the myenteric plexus. Several reports suggest the efficacy of cisapride in managing intestinal disease in horses, including the resolution of persistent large colon impaction, treatment of equine grass sickness, and as a preventative for POI in horses after small intestinal surgery (0.1 mg/kg body mass intramuscularly during the postoperative period).[50–53] The horse erratically absorbs tablets administered rectally, but a method for preparing a parenteral form of the drug from tablets has been described.[54] Cisapride has the potential to cause adverse cardiac side effects mediated through blockage of the rapid component of the delayed rectifier potassium current that include lengthening of the QT interval and development of torsades de pointes, a potentially fatal arrhythmia. These adverse effects have resulted in withdrawal of the drug in the United States.

Domperidone acts as a competitive antagonist at peripheral DA_2 receptors. The drug is a therapeutic agent (1.1 mg/kg/day) for mares grazing endophyte-infected tall fescue, principally because of drug-enhanced prolactin release. The potential prokinetic effects of domperidone have not been studied extensively in horses, but a modest efficacy of domperidone (0.2 mg/kg intravenously) has been demonstrated in experimental ileus in two ponies.

Erythromycin is a direct motilin receptor agonist on smooth muscle cells and also may act within the enteric nervous system to facilitate the release of acetylcholine and motilin. Erythromycin enhances gastric emptying in normal horses but has a more pronounced effect on the hindgut.[47,55] Erythromycin lactobionate (1.0 mg/kg intravenously) hastens cecal emptying in normal animals and induces colonic MMC-like activity across the colon. Administration often is associated with defecation and abdominal discomfort. The drug may help prevent cecal impaction in horses after anesthesia, although its effectiveness on cecal motility in the immediate postoperative period may be reduced.[36] High doses, constant infusion, or prolonged use of erythromycin induces receptor downregulation and inhibition of activity. Erythromycin can induce diarrhea in adults, therefore one should avoid dosing over many days.

Naloxone (0.05 mg/kg intravenously) induces contractile activity in the cecum and left colon.[56] Defecation commonly follows administration of naloxone within 15 to 20 minutes.

α_2-Adrenoreceptor antagonists such as yohimbine or tolazoline counteract increased sympathetic outflow in response to nociceptive stimulation. Yohimbine infusion (75 µg/kg) also may attenuate the negative effects of endotoxin on motility.[32]

Intravenous infusion of lidocaine may suppress primary afferent neurons, thereby limiting reflex efferent inhibition of motility. An infusion dose of 15 to 20 mg/min over 5 to 6 hours has been recommended for horses. 819

Lidocaine infusion is associated with reversible side effects that include muscle fasciculations, ataxia, and seizure. Consequently, the rate of infusion requires close monitoring. 820

13.7—Endotoxemia

Katharina L. Lohmann

Michelle Henry Barton

13.7.1

Introduction and Definitions

Endotoxemia is defined as the presence of endotoxin in the bloodstream. Most often, however, the term is used to refer to the associated clinical manifestations caused by an overshooting inflammatory reaction. In its pathophysiologic consequences the innate immune response to endotoxin (lipopolysaccharide) is similar to the response to other stimuli; for example, overwhelming bacterial infection, viral infection, or severe trauma. The term *systemic inflammatory response syndrome* therefore was introduced to describe a general systemic inflammatory process independent of cause. *Sepsis* is defined as the “systemic inflammatory response to infection,” and *septic shock* as “sepsis-induced hypotension, persisting despite adequate fluid resuscitation, along with the presence of hypoperfusion abnormalities or organ dysfunction.”[1] According to these definitions the

diagnosis of sepsis requires documentation of infection by culture in addition to two or more of the following findings: hypo- or hyperthermia, tachycardia, tachypnea or hypocapnia, and leukocytosis, leukopenia, or an increased proportion of immature leukocyte forms. Organ failure is a common sequela of endotoxic or septic shock, and the term *multiple organ dysfunction syndrome* describes insufficiency of two or more organ systems, as evident by clinical or clinicopathologic changes. In horses one should include the laminae of the feet in the list of organs susceptible to failure.

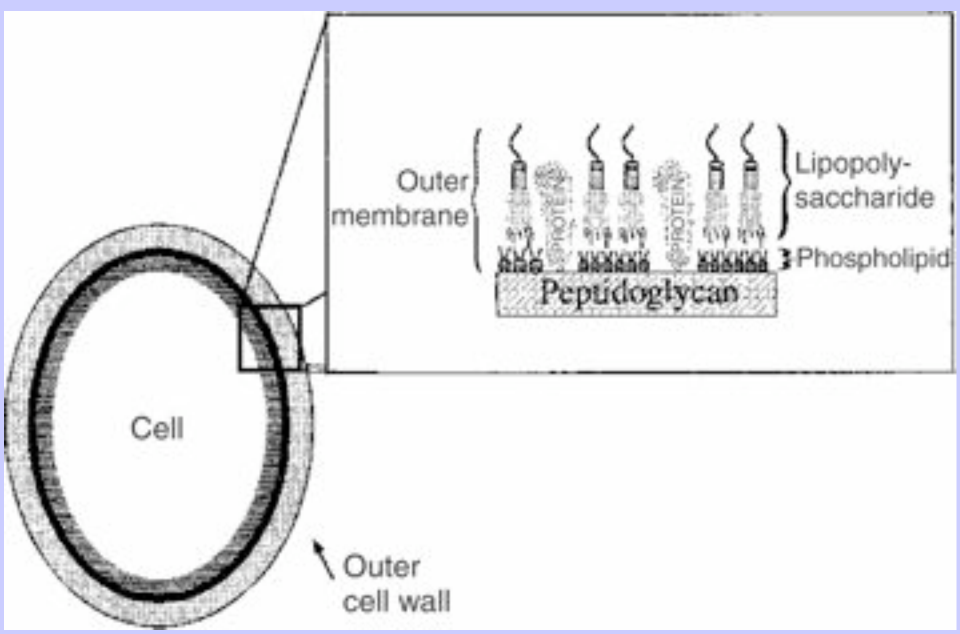
13.7.2 Endotoxin

German scientist Richard Pfeiffer (1858–1945), in working with *Vibrio cholerae,* first described endotoxin as a toxin "closely attached to, and probably integral of, the bacterial body."[2] He observed this toxin to be distinct from the actively secreted, heat-labile, and proteinaceous bacterial exotoxins. Endotoxin later was found to be a heat-stable lipopolysaccharide structure, and the terms *endotoxin* and *lipopolysaccharide* now are used interchangeably.

Lipopolysaccharide is a major structural cell wall component of all gram-negative bacteria, including noninfectious species (Figure 13.7-1). With 3 to 4 × 10[6] molecules per cell, lipopolysaccharide makes up about 75% of the outer layer of the outer cell membrane and is a key functional molecule for the bacterial outer membrane, serving as a permeability barrier against external noxious agents. The lipopolysaccharide molecule 821

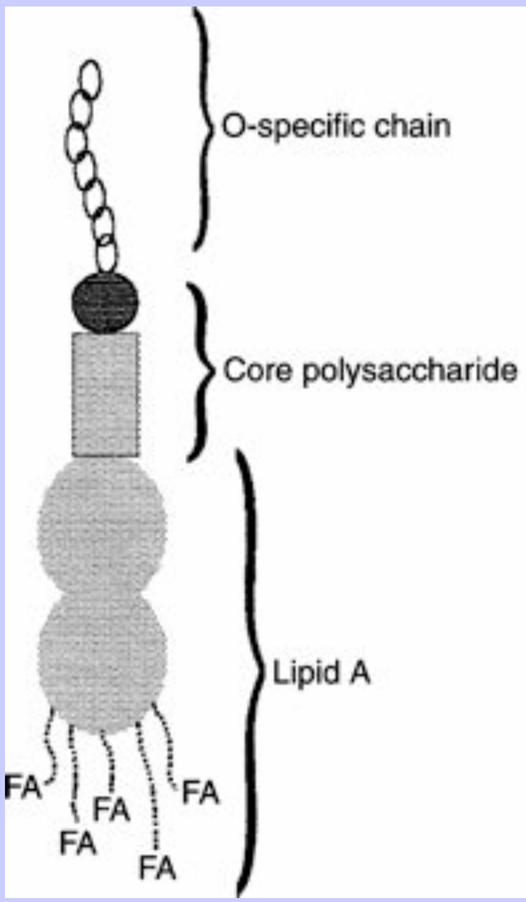
822 consists of four domains, which are essential for the virulence of gram-negative bacteria.[3] Three of the domains (inner core, outer core and O-specific chain) represent the hydrophilic polysaccharide portion of the molecule, whereas the lipid A portion represents the hydrophobic lipid portion (Figure 13.7-2). Combined, these domains confer the overall amphiphilic properties of the molecule that lead to the formation of micellar aggregates in aqueous solutions.

Figure 13.7-1



O-specific chains (also called O-antigen polysaccharides or O-chains) are characteristic of any given type of lipopolysaccharide and show enormous structural variability between bacterial serotypes.[4] O-chains are synthesized by addition of preformed oligosaccharide blocks to a growing polymer chain and therefore have a repetitive structure. O-specific chains determine part of the immunospecificity of bacterial cells[5] and, on interaction with the host immune system, serve as antigens for the production of species-specific antibodies.[6] O-specific chains are further responsible for the smooth appearance of gram-negative bacterial colonies on culture plates,[3] and lipopolysaccharide molecules containing an O-chain are termed *smooth lipopolysaccharide*.

Figure 13.7-2



The inner (lipid A-proximal) and outer (O-chain-proximal) core oligosaccharide portion is more conserved between different strains of gram-negative bacteria than the O-specific chain.[4] The core of all lipopolysaccharide molecules contains the unusual sugar KDO (3-deoxy-D-manno-oct-2-ulopyranosonic acid), which links the core region to the lipid A molecule. Synthesis of a minimal core is essential for the survival of bacteria,[7] and the smallest naturally occurring lipopolysaccharide structure consists of lipid A and KDO.[8] In contrast to the S-form colonies, colonies of gram-negative bacteria with lipopolysaccharide molecules that lack the O-specific chai n but contain a core region show a rough appearance on culture plates. Rough lipopolysaccharide molecules are denoted further as Ra, Rb, etc. to indicate the length of the core region. In Re-lipopolysaccharide (also called

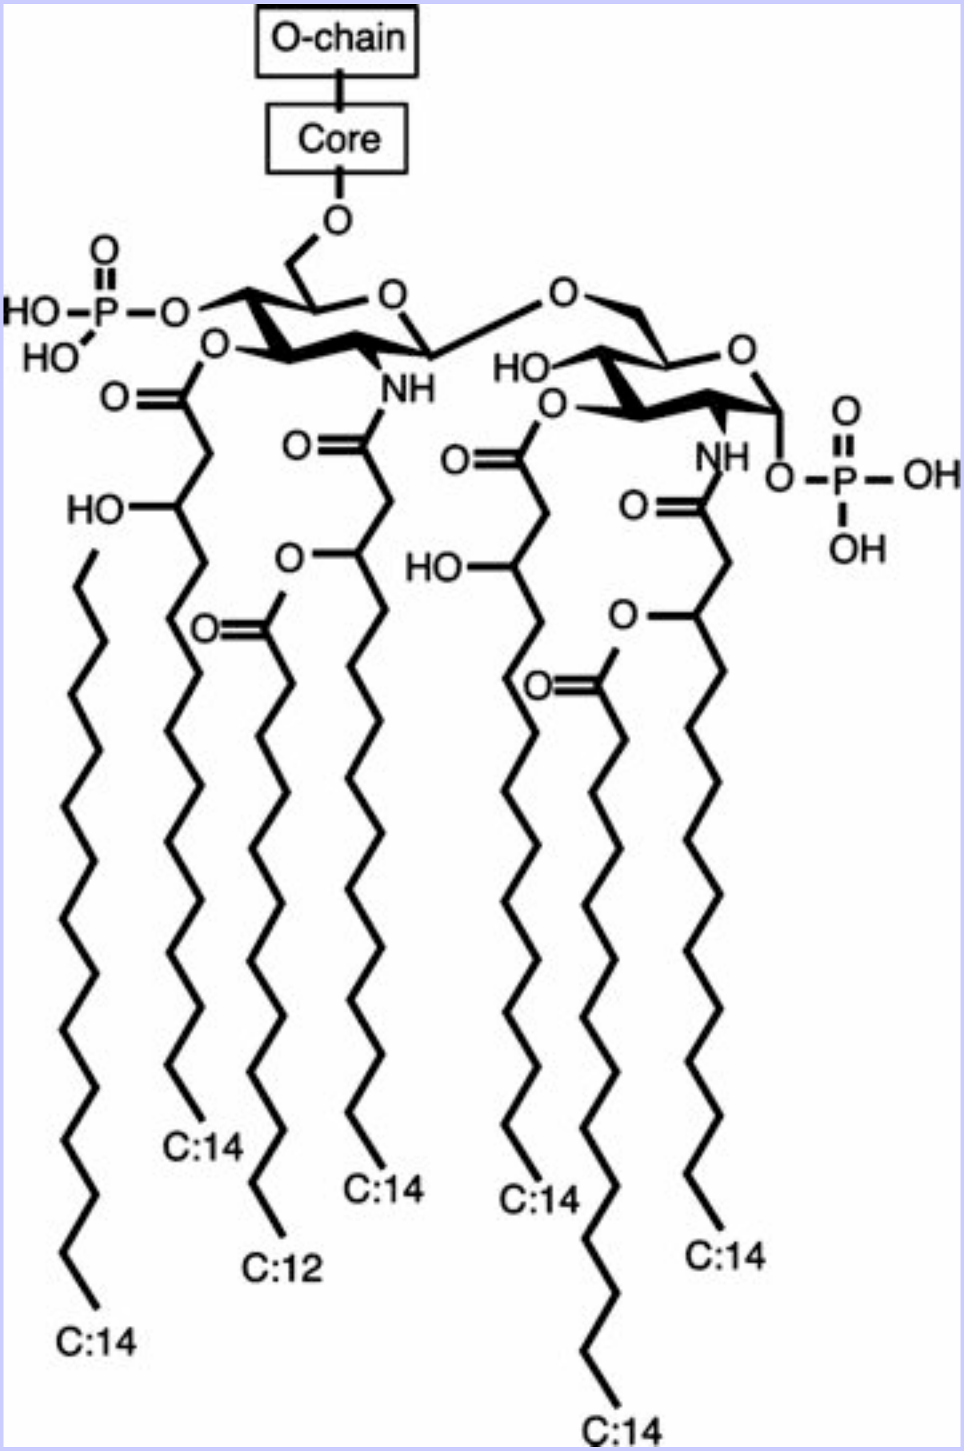
deep rough lipopolysaccharide), the core region is reduced to a KDO residue. Remutants often are used to raise antibodies against the core region in an attempt to provide cross-protection against a variety of bacterial species.

The lipid A portion serves to anchor the lipopolysaccharide molecule in the bacterial outer membrane and has been identified as the toxic principle of lipopolysaccharide,[9] and its structure is highly conserved among gram-negative bacteria. The common structure shared by lipid A molecules is a 1,4′-bisphosphorylated β1,6-linked D-glucosamine disaccharide backbone (lipid A backbone), which is acylated by up to six fatty acids.[4] Figure 13.7-3 shows the acylation pattern for *Escherichia coli* lipopolysaccharide. Variation in the lipid A structure between gram-negative bacteria affects the number, length, and position of fatty acids and the backbone structure and the substitution of phosphate by other polar groups.[6]

13.7.3 Causes of Endotoxemia in Horses

According to its nature as a structural cell wall component, the presence of endotoxin implies the presence of gram-negative bacteria as a source. Depending on the nature of the underlying disease, these bacteria may circulate in the bloodstream in their intact form (i.e., bacteremia), may be confined to a localized infectious process, or may be part of the endogenous bacterial flora colonizing the gastrointestinal tract. In any of these scenarios, endotoxin molecules are released as a by-product of bacterial growth and in large numbers on bacterial
cell death.[10] Common infectious conditions associated with endotoxemia in horses include neonatal gram- 822
negative sepsis, bacterial pneumonia and pleuropneumonia, endometritis, peritonitis, and infectious colitis with 823
bacteria such as *Salmonella* spp., that are not part of the normal intestinal flora. In one study, for example, endotoxin was detectable in plasma of 50% of foals evaluated for presumed sepsis.[11]

Figure 13.7-3 Chemical structure of the lipid A backbone. *C:14,* Myristic acid, *C:12,* lauric acid.



The term *translocation* describes entry of endogenous bacteria and bacterial products from the gastrointestinal tract into tissues and the systemic circulation.[12] The natural intestinal flora of horses consists mainly of gram-negative, anaerobic bacteria, and thus large amounts of endotoxin normally exist in the lumen of the equine intestinal tract.[13] Even in health, small amounts of endotoxin cross the intact mucosal barrier and reach the portal circulation and the liver. These molecules are cleared, however, by the mononuclear phagocytic system in the liver and only lead to a localized and restricted activation of the host immune system. For endotoxin translocation to become detrimental, excessive amounts have to cross the intestinal barrier and overwhelm the mononuclear phagocytic system or the capacity of the liver to detoxify lipopolysaccharide must be compromised. The latter may be a concern in conditions such as hepatitis, cholangiohepatitis, or portosystemic shunting of blood.

Permeability of the intestinal mucosal barrier frequently increases in cases of acute gastrointestinal disease. Colic patients are prime candidates to development endotoxemia, and plasma endotoxin was detectable in 10% to 40% of colic patients on admission.[14,15] A higher percentage of horses tested positive for endotoxin when only patients presented for surgical intervention were evaluated.[15] Aside from gastrointestinal rupture, increased permeability to intact bacteria or free endotoxin molecules is thought to be associated most commonly with ischemic insults such as strangulating obstruction and bowel infarction, severe inflammation as in proximal enteritis and colitis, bacterial overgrowth, and intraluminal acidosis, which occurs with grain overload.[16,17] One study, however, found no difference in plasma endotoxin detection between disease groups, therefore emphasizing the fact that any disease of the abdominal cavity can induce endotoxemia in horses. In the same study, endotoxin was approximately 3 times more likely to be detected in peritoneal fluid as opposed to plasma samples. Similarly, higher cytokine concentrations have been measured in peritoneal fluid than in plasma. The likely explanation for these findings is a local inflammatory response in the peritoneal cavity elicited by translocated bacteria and/or lipopolysaccharide molecules before their absorption into the systemic circulation.[14]

Although certainly the most important factor in horses, conditions other than gastrointestinal disease may result in translocation of endotoxin and bacteria. In experimental studies using laboratory animals, entry of gut-associated bacteria into the lymphatic system was demonstrated after hypovolemic shock, burn injuries, trauma, malnutrition, and starvation.[18–20] Furthermore, endotoxin itself caused bacterial translocation into mesenteric lymph nodes after intraperitoneal administration to mice.[21] These findings have received much attention in the literature concerning human patients because they serve to explain cases of endotoxic shock in the absence of demonstrable bacterial infection. One should keep in mind the possibility of translocation when evaluating cases of presumed systemic inflammatory response syndrome in horses, in which one cannot demonstrate bacterial infection or gastrointestinal disease. Endotoxin translocation also may be associated with strenuous exercise, which results in reduced splanchnic blood flow, hypoxemia, and a higher body temperature. In fit racehorses a significantly increased mean plasma lipopolysaccharide concentration was found after racing, whereas antilipopolysaccharide immunoglobulin G levels were decreased. Fit horses showed significantly higher 823
antilipopolysaccharide immunoglobulin G concentrations at rest than sedentary controls, suggesting leakage of 824
small amounts of endotoxin from the intestinal lumen during training and racing.[22] The clinical significance of these findings requires further investigation.

13.7.4 Mechanisms of Cellular Activation by Lipopolysaccharide

The initiating event in the pathophysiology of endotoxemia is the activation of lipopolysaccharide-responsive cells by endotoxin, resulting in altered cellular functions and increased expression of inflammatory mediators.

Immune cells such as macrophages, which are the first to encounter endotoxin, respond to minute amounts of lipopolysaccharide, which usually allows them to eliminate gram-negative bacteria and free lipopolysaccharide molecules efficiently. An important factor in the exquisite sensitivity to lipopolysaccharide is the presence of lipopolysaccharide-binding protein (LBP).[4] LBP is an approximately 60-kd plasma glycoprotein[23] synthesized by hepatocytes[24] and belongs to the group of acute phase proteins. Under the control of inflammatory agents and cytokines, LBP concentration in plasma increases approximately 100-fold within 24 hours of an inflammatory stimulus.[25] The main function of LBP is to transfer lipopolysaccharide to endotoxin-responsive cells, which include mononuclear phagocytes, neutrophils, lymphocytes, and endothelial cells. The importance of a highly sensitive response to lipopolysaccharide for protection against gram-negative bacterial infection is demonstrated in experiments using LBP “knock-out” mice (mice that lack the LBP gene and are therefore unable to synthesize LBP). Although these animals are resistant to the effects of isolated lipopolysaccharide, they are unable to control bacterial infection and rapidly succumb.[26] Despite its crucial importance for an effective host defense, LBP is not essential for lipopolysaccharide-receptor interaction per se, because high concentrations of lipopolysaccharide can activate cells in the absence of LBP.[27]

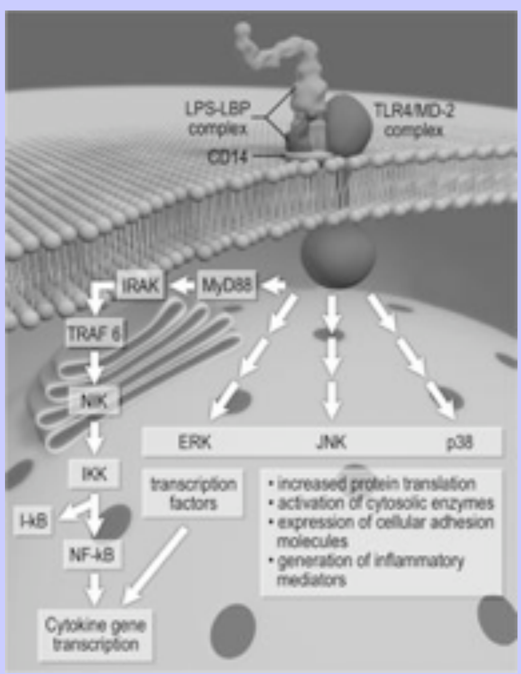
Aside from its role as a catalyst of cellular activation by lipopolysaccharide, LBP has opsonizing activity[28] and participates in the phagocytosis of lipopolysaccharide by macrophages and neutrophils.[29,30] Although phagocytosis of lipopolysaccharide is receptor dependent, it appears to be uncoupled from intracellular signaling events and occurs in the absence of cell activation.[31] LBP further catalyzes transfer of lipopolysaccharide to lipoproteins such as high-density lipoprotein, which neutralizes lipopolysaccharide activity.[32] This detoxifying effect may become important when large amounts of lipopolysaccharide are present. A protective effect of LBP against lipopolysaccharide challenge and infection has been demonstrated in a murine model.[33]

The most important lipopolysaccharide receptors known to date are cluster differentiation antigen 14 (CD14)[27] and Toll-like receptor 4 (TLR4).[34] Both are classified as pattern recognition receptors,[35] which means that they recognize lipopolysaccharide as a pattern common to all gram-negative bacteria. CD14 is a 53-kd protein that in its membrane-bound form (mCD14) is inserted into the cell membrane via a glycosyl-phosphatidyl-inositol anchor.[36] CD14 is expressed primarily on monocytes and tissue macrophages and to a lesser extent on neutrophils.[37] CD14 also is found in a free, or soluble, form (sCD14)[38] that can bind to cell types lacking CD14, such as endothelial cells, and make them lipopolysaccharide-responsive. In addition to this proinflammatory effect, high concentrations of sCD14 can sequester and neutralize lipopolysaccharide.[39] The amount of circulating sCD14 greatly increases during inflammation, which makes it a useful marker of acute and chronic inflammation.[37]

Although CD14 is known to be crucial for cellular activation, it cannot transmit signals to the inside of the cell because it lacks a transmembrane domain. The missing link between CD14 and the cytosolic environment is a Toll-like receptor in association with a molecule named MD-2.[40] The name *Toll-like receptor* stems from the homology of the mammalian receptor with a receptor type in *Drosophila* (Toll) that is important for dorsoventral orientation and immune responses in the fly. A number of Toll-like receptors have been identified in mammalian species so far, but TLR4 appears to be the receptor subtype most important for lipopolysaccharide signaling.[34] The importance of CD14 and TLR4 in the cellular response to lipopolysaccharide has been demonstrated in a number of experiments. Mice deficient in CD14 are incapable of mounting a normal inflammatory response to lipopolysaccharide,[39] whereas mutation or deletion of the gene encoding for TLR4 causes lipopolysaccharide hyporesponsiveness.[41–43]

After binding of lipopolysaccharide to cellular receptors, a multitude of signaling events takes place within the
cell and results in the alterations of cellular metabolism known as cell activation. Signaling pathways are
characterized by sequential phosphorylation and thereby activation of enzymatic activities. A typical end result
of intracellular signaling is the activation of transcription factors; for example, proteins that bind to DNA and
promote gene transcription. Translational mechanisms are activated in a similar manner. Among the best-
characterized pathways in endotoxin-induced cell signaling are the mitogen-activated protein kinase (MAPK)
pathways and the activation of transcription factor nuclear factor κB (NFκB) (Figure 13.7-4).[44,45] In the NFκB
pathway the intracellular domain of TLR4 associates with the adapter protein myeloid differentiation factor 88 824
and recruits interleukin-1 receptor-associated kinase to the complex. Activation of interleukin-1 receptor- 825
associated kinase, tumor necrosis factor receptor-associated factor, NFκB-inducing kinase, and IκB-kinase
follow, and lastly, IκB is phosphorylated. IκB is an inhibitor protein complex that sequesters and inactivates
NFκB in the cytoplasm. On phosphorylation, IκB is ubiquinated and degraded, and NFκB is translocated to the
nucleus where it unfolds its activity.[46] NFκB is a dimeric protein complex with several isoforms of which the
p65/p50 heterodimer is the most important inducible complex in mammals.[47] Proteins of importance for the 825
pathogenesis of septic shock, the genes of which contain promoter elements for NFκB, include cytokines, 826
inducible nitric oxide synthase, and cyclooxygenase 2 (COX-2).[44]

Figure 13.7-4 Mechanisms of cell activation by endotoxin. Lipopolysaccharide-binding protein *(LPB)* associates with lipopolysaccharide (*LPS*, endotoxin) and transfers it to the cellular surface, where lipopolysaccharide interacts with a receptor complex comprising CD14, Toll-like receptor 4 *(TLR4)*, and MD-2. Toll-like receptor 4, but not CD14, possesses a transmembrane portion and allows signal transduction to the cytosol. Signaling via the mitogen-activated protein kinases including extracellular signal-regulated kinase *(ERK)*, c-Jun-terminal kinase *(JNK)*, and p38 results in numerous alterations of cellular metabolism. Activation of IκB-kinase *(IKK)* via sequential phosphorylation of myeloid differentiation factor 88 *(MyD88)*, interleukin-1 receptor-associated kinase *(IRAK)*, tumor necrosis factor receptor–associated factor *(TRAF 6)*, and NFκB-inducing kinase *(NIK)* leads to phosphorylation, ubiquination, and degradation of IκB and release of NFκB. Transcription factors such as NFκB translocate to the nucleus and promote gene transcription. See the text for further details and alternative pathways of cellular activation.



Three groups of MAPKs known to be crucially important for lipopolysaccharide-induced signal transduction are extracellular signal-regulated kinase, c-Jun-terminal kinase, and p38. Final effects of signaling through MAPK pathways include the activation of several transcription factors, translation initiation factors, and cytosolic enzymes such as phospholipase A_2, as well as an increase in the expression of adhesion molecules on the cell surface.[44] Despite the characterization of seemingly separate pathways, one should recognize that interaction and synergy between pathways is likely to occur. For example, simultaneous activation of p38, c-Jun-terminal kinase, and extracellular signal-regulated kinase results in much higher levels of tumor necrosis factor (TNF) reporter expression than activation of a single pathway.[44,48] Aside from the mechanisms described here, pathways involving atypical protein kinase C[49,50] and receptor-independent integration of lipopolysaccharide into the cell membrane and ceramide-like second messenger activity of lipopolysaccharide[37] have been proposed. Additional pathways are likely to be uncovered in the ongoing investigation of intracellular signaling mechanisms and their in vivo significance.

13.7.5 Inflammatory Mediators

Although endotoxin can exert some direct effects, cytokines are a primary mediator of lipopolysaccharide effects. Cytokines are glycoprotein molecules that regulate inflammatory and immune responses by acting as a signal between cells.[51] Cytokines of major interest in the pathogenesis of endotoxemia include TNF, the interleukins, chemokines, and growth factors such as granulocyte-monocyte colony-stimulating factor. TNF is thought of as the most “proximal” cytokine released in response to lipopolysaccharide. Studies corroborate this by showing that administration of recombinant TNF mimics the effects of lipopolysaccharide,[52] and that antibodies directed against TNF protect against the lethal effects of endotoxin.[53] Increased plasma activity of TNF is associated with increased mortality in equine patients with acute gastrointestinal disease and in septic neonates.[14] Despite being a structurally diverse group of proteins, cytokines share several characteristics that allow them to execute their complex functions in the inflammatory response.[51] Any individual cytokine generally is produced by several different cell types, can act on different cell types, and has multiple effects on any given cell. Furthermore, cytokine effects are redundant, meaning that different cytokines can share the same effect. In endotoxemia, this is particularly true for the effects of interleukin-1 (IL-1) and TNF.[54] Many of the biologic activities of cytokines in vivo result from synergistic or antagonistic actions involving two or more cytokines.[55] Within itself the cytokine response is highly regulated: cytokines induce or suppress synthesis of other cytokines including their own (feedback regulation), regulate expression of cytokine receptors, and regulate cytokine activities. Additional regulatory mechanisms include the release of specific cytokine inhibitors such as soluble IL-1 and TNF-α receptors, cytokine receptor antagonists such as IL-1 receptor antagonist, and antiinflammatory cytokines including IL-10, IL-4, IL-13, and transforming growth factor β. Glucocorticoids also are produced increasingly in response to endotoxin and inhibit the production of cytokines.[56] During a controlled inflammatory response, therefore, cytokine secretion is a self-limited event, whereas excessive stimulation of cytokine release can lead to the perpetuation of the inflammatory response even after the initial stimulus has been removed. Conversely, the compensatory antiinflammatory reaction can become severe enough to cause anergy of the immune system and increased susceptibility to infection, which has been termed the *compensatory antiinflammatory response syndrome*. Overall, excessive and unbalanced stimulation of the immune system therefore may result in predominantly proinflammatory (systemic inflammatory response syndrome), antiinflammatory (compensatory antiinflammatory response syndrome), or combined (mixed antagonist response syndrome) responses.[57]

Interestingly, tolerance to endotoxin develops after repeated exposure to lipopolysaccharide.[58] Tolerance can be demonstrated in vitro and in vivo and encompasses decreased production of cytokines and a diminished clinical response.[58,59] Mechanisms that likely are responsible for the development of endotoxin tolerance include receptor downregulation and inhibition of intracellular signaling pathways.[60,61] Cytokines such as TNF are important mediators in the development of endotoxin tolerance.[62] The development of endotoxin tolerance in horses has been reported.[63,64]

Aside from cytokines, a number of other molecules function as inflammatory mediators in the pathogenesis of endotoxemia, the synthesis and release of which are stimulated by endotoxin and by cytokines. These mediators include the arachidonic acid metabolites or prostanoids, platelet-activating factor (PAF), oxygen-derived free radicals, nitric oxide (NO), histamine, kinins, and complement components. Table 13.7-1 summarizes the origins, targets, and effects of the most important inflammatory mediators involved in the pathogenesis of endotoxemia. Figure 13.7-5 shows the pathways of arachidonic acid metabolism by COX and lipoxygenase. COX products are the prostaglandins (PGs), prostacyclin (PGI_2) and thromboxanes, and the lipoxygenase produces the leukotrienes. 826

TABLE 13.7-1 Important Mediators of the Systemic Inflammatory Response to Endotoxin

MEDIATOR	ORIGIN	EFFECTS
Tumor necrosis factor	Macrophages	Induces synthesis of TNF, IL-1, IL-6, and GM-CSF.*
	Monocytes	Activates neutrophils.
	Neutrophils	Activates fibrinolysis and coagulation.
	$CD4^+$ T cells	Activates contact and complement system.
	Natural killer cells	Induces a catabolic state.
		Induces insulin resistance.
		Is a pyrogen (direct action and via IL-1 induction).
		Induces synthesis of TNF, IL-1, IL-6, PGI_2, PAF, and GM-CSF.
Interleukin-1	Activated macrophages	Activates pyrogen.
	Endothelial cells	Induces malaise.
	Fibroblasts	Activates neutrophils and chemotaxis.
	Dendritic cells	Activates fibrinolysis and coagulation.
	Lymphocytes	Activates contact and complement system.
	Keratinocytes	Induces acute phase response.
		Increases activity of lipoprotein lipase.
		Mobilizes amino acids.
		Induces muscle proteolysis.
Interleukin-6	Activated macrophages	Induces acute phase response.
	Fibroblasts	Induces stress response.
	Keratinocytes	Is a weak pyrogen.
	T lymphocytes	
Interleukin-8	Macrophages	Activates neutrophils and chemotaxis.
	Endothelial cells	
Thromboxane A_2	Platelets	Induces vasoconstriction.
		Activates platelet aggregation.
Prostaglandin E_2	Most nucleated cells	Induces vasodilation.
		Activates platelet aggregation.
		Induces fever.

Prostaglandin I_2	Vascular endothelial cells	Induces vasodilation.
		Inhibits platelet aggregation.
Platelet-activating factor	Macrophages	Activates platelet aggregation.
	Platelets	Activates macrophages and neutrophils.
	Neutrophils	Induces hypotension.
	Mast cells	Increased vascular permeability.
	Eosinophils	Aids recruitment of leukocytes.
		Induces visceral smooth muscle contraction.
		Is a negative inotrope and arrhythmogenic.
		Induces ileus.
Prostaglandin $F_{2\alpha}$	Most nucleated cells	Induces vascoconstriction.
		Activates luteolysis.
Leukotriene B_4	Most nucleated cells	Is a chemoattractant.
		Promotes neutrophil interaction with endothelial cells.
Leukotrienes C_4, D_4, E_4	Most nucleated cells	Increase vascular permeability.
		Induce bronchoconstriction.
		Induce vasoconstriction.
Kinins	Produced from serum precursors	Increase vascular permeability.
		Induce smooth muscle contraction.
		Cause pain.
Complement components (C3a, C5a)	—	Activate neutrophils and chemotaxis.
		Induce smooth muscle constriction.
		Induce mast cell degranulation.
		Induce release of histamine and serotonin.
		Increase vascular permeability.
Oxygen-derived free radicals	Macrophages	Damage cell membranes.
	Neutrophils	Inactivate enzymes.
		Damage tissues.
Granulocyte-monocyte colony-stimulating factor	—	Induces rebound neutrophilia.

* *TNF,* Tumor necrosis factor; *IL,* interleukin; *GM-CSF,* granulocyte-monocyte colony-stimulating factor; *PG,* prostaglandin; *PAF,* platelet-activating factor.

13.7.6

Pathogenesis

The innate immune response to lipopolysaccharide is an efficient defense mechanism that provides maintenance of homeostasis and therefore health in the face of an almost continuous exposure to microorganisms and their products.[65] Detrimental consequences of this immune response only occur if excessive and uncontrolled mediator output results in endothelial damage, neutrophil-mediated tissue damage, and uncontrolled activation of the coagulation and fibrinolytic cascades and the complement system. Ultimately, the combination of these events culminates in cardiovascular instability, impaired hemostasis, organ failure, shock, and death. The following discussion addresses the various pathophysiologic events in the development of endotoxemia and shock and the role of inflammatory mediators.

13.7.6.1

ENDOTHELIAL DYSFUNCTION AND DAMAGE

Normal endothelium plays an important role in regulating blood pressure and regional tissue perfusion and provides an anticoagulant surface. Endothelial dysfunction and damage result in a decreased responsiveness to vasoactive agents (vasoplegia), increased vascular permeability, and a tendency for clot formation in the microvasculature. If the basement membrane and underlying matrix are compromised, further microvascular hemorrhage can occur. Endothelial cell damage is primarily neutrophil-mediated. More specifically, damage is

caused by oxygen-derived free radicals, which are produced within endothelial cells via reactions involving neutrophil-derived elastase and hydrogen peroxide molecules, endothelial cell enzymes such as xanthine oxidase, and endothelial cytosolic iron. The hypochloric anion radical (HO$^{\cdot}$) is thought to be responsible most directly for endothelial cell cytotoxicity. NO$^{\cdot}$ produced by constitutively expressed nitric oxide synthase in endothelial cells may afford protection from oxygen radical–induced endothelial cell damage. NO is able to scavenge superoxide radicals and react with them to form peroxynitrite. Variations in the ability to produce NO may explain why vascular beds in different organs vary in their susceptibility to neutrophil-mediated 828
damage.[66] Excessive production of NO by an inducible form of nitric oxide synthase (*i*NOS), however, 829
contributes to tissue damage, and increased peroxynitrite concentrations may be responsible in part for PAF-induced increases in vascular permeability.[67] In addition to oxygen-derived free radicals, activated neutrophils release matrix metalloproteinases, which contribute to tissue damage.[56] Vascular endothelial cells are further susceptible to direct effects of various cytokines, most prominently TNF-α and IL-1. These cytokines are thought to cause damage via the induction of COX activity and production of prostanoids and through generation of free radicals.

13.7.6.2 NEUTROPHIL ACTIVATION, MARGINATION, AND TRANSMIGRATION

Neutrophil activation by lipopolysaccharide and cytokines results in stimulation of phagocytosis and the respiratory burst, release of lysosomal enzymes and inflammatory mediators, and expression of adhesion molecules. Perhaps the single most specific clinicopathologic indicator of endotoxemia is pronounced neutropenia,[68] which temporally correlates with peak plasma concentrations of TNF.[69] Neutropenia is caused primarily by margination of neutrophils in the vasculature, whereas significant loss through active migration into peripheral tissues likely is limited to the presence of a localized source of infection. Margination is made possible by adhesion molecules on endothelial cells and leukocytes that interact and allow sticking of leukocytes to the endothelial lining of blood vessels. Endotoxin or cytokines such as TNF and IL-1 can initiate expression of adhesion molecules.[70] Subsequent transmigration of cells into tissue spaces is aided by the production of leukocyte collagenase, which allows enzymatic destruction of the vascular basement membrane. Margination and transmigration of neutrophils occurs in three phases.[70,71] In the first phase of tethering and rolling, endothelial cells are stimulated to express P-selectin and E-selectin, which bind to P-selectin glycoprotein ligand-1 and sialylated Lewis-X–like structures on leukocytes, respectively. Whereas P-selectin is stored preformed in Weibel-Palade bodies of endothelial cells, E-selectin is expressed only following stimulation by cytokines. Additionally, constitutively expressed L-selectin on neutrophils can bind to endothelial glycoproteins and glycolipids. During the second phase, firm adhesion is mediated by binding of neutrophil integrins (LFA-1 and Mac-1, also known as CD11a/CD18 and CD11b/CD18) to intercellular adhesion molecule 1 (an immunoglobulin structure) on endothelial cells. Although integrins are expressed constitutively on the leukocyte surface, activation signals are necessary to induce a high-affinity state and interaction with the endothelial surface. Transmigration finally requires the expression of yet another adhesion molecule, namely platelet/endothelial cell adhesion molecule 1, which is located at the intercellular junction of endothelial cells.[71] Chemotactic factors including activated complement factor C5a and the CXC chemokines control transmigration.[66] The latter group includes IL-8, which is expressed by endothelial cells in response to activation. Rebound neutrophilia, which is observed frequently following episodes of endotoxemia, is caused by neutrophil release from the bone marrow reserve pool and by stimulation of myeloid cell proliferation via granulocyte-macrophage colony-stimulating factor and is mediated primarily by TNF and IL-1.[54]

13.7.6.3

COAGULOPATHY AND DISSEMINATED INTRAVASCULAR COAGULATION

In health, coagulation and fibrinolysis underlie stringent control mechanisms that allow appropriate clot formation and their resolution. Coagulopathies frequently are observed in horses with colic[16,72,73] and foals with sepsis[11] and are likely attributable to endotoxemia. Disseminated intravascular coagulation (DIC) results from a widespread activation of the coagulation and fibrinolytic systems and failure of their control mechanisms. Ultimately, this leads to disseminated fibrin deposition in the microvasculature, consumption of platelets and clotting factors, and accumulation of fibrin degradation products (FDPs). Depending on the underlying disease process and the impairment of the systems, DIC can manifest as a diffuse thrombotic syndrome leading to ischemic organ failure, a fibrinolytic syndrome with uncontrolled hemorrhage, or a combination of both.[74] A procoagulant state in which one can detect clinicopathologic abnormalities precedes DIC.

Activation of the coagulation cascade culminates in the cleavage of fibrinogen to fibrin by the serine protease thrombin. Thrombin deposition on endothelial cell surfaces leads to platelet adherence and their activation by surface-bound PAF.[56] The intrinsic and extrinsic arms of the coagulation cascade are activated in endotoxemia. The intrinsic pathway is initiated by activation of coagulation factor XII (Hageman factor), prekallikrein, and high-molecular-weight kininogen, which compose the contact system.[75] Although direct activation of coagulation factor XII by endotoxin has been demonstrated,[76] the extrinsic pathway likely is more important for the development of coagulopathy in endotoxemia and sepsis.[75] Activation of the extrinsic pathway depends on the interaction of coagulation factor VII with tissue factor, which is the only coagulation factor not constitutively present in blood. Tissue factor is present in subendothelial tissues and is exposed on vascular injury but also is expressed on endothelial cells and mononuclear phagocytes in response to lipopolysaccharide.[77,78] Increased expression of monocyte tissue factor (also described as increased procoagulant activity) was found to be associated significantly with coagulopathy and poor prognosis in 829
horses with colic.[79] Furthermore, lipopolysaccharide-induced tissue factor expression by equine peritoneal 830
macrophages may be associated with the development of intraabdominal adhesions.[63]

Regulatory mechanisms of the coagulation cascade include tissue factor pathway inhibitor, antithrombin III (AT III), and the protein C system.[75] Protein C acts as an anticoagulant by inactivating clotting factors V and VIII and promotes fibrinolysis by inactivating plasminogen activator inhibitor (PAI).[80] Protein C activation by thrombin-thrombomodulin complexes is important for the anticoagulative properties of normal endothelium,[75] and downregulation of endothelial thrombomodulin expression by TNF and IL-1 and decreased expression of AT III and tissue factor pathway inhibitor by damaged endothelial cells contribute to the procoagulant state in endotoxemia and sepsis.[81–83] In addition, activation of vascular endothelial cells leads to a loss of prostacyclin and NO production and an increased release of thromboxane A_2 (TXA_2). As a result, platelets are stimulated to aggregate and release TXA_2 and PAF, thereby further promoting clot formation.[17]

The crucial step in the fibrinolytic cascade is the conversion of plasminogen to plasmin, a fibrin-degrading enzyme.[75] Tissue-type (tPA) and urokinase-type (uPA) plasminogen activator are the major initiators of fibrinolysis, whereas PAI and α_2-antiplasmin are the main regulatory components.[84,85] TNF and IL-1 have been shown to induce the release of uPA and tPA and the synthesis of PAI.[75] Activation of fibrinolysis leads to consumption of α_2-antiplasmin and accumulation of FDPs, which if present in high concentrations can

interfere with platelet aggregation, fibrin polymerization, and thrombin formation and can promote bleeding. Additionally, FDPs mediate an increase in vascular permeability. Lipopolysaccharide infusion in rabbits[86] and human beings[87] resulted in an early increase in plasma tPA activity, followed by a later profound rise in PAI activity and fall in tPA activity. Increased plasma PAI concentrations also were found in horses with colic compared with controls.[88,89] Thus although fibrinolysis may compensate initially for accelerated coagulation, its subsequent inhibition contributes to clot formation.

13.7.6.4 COMPLEMENT ACTIVATION

Activation of the complement system in endotoxemia occurs via the alternative pathway through interaction with lipopolysaccharide. Increased concentrations of plasmin and kallikrein (caused by activation of the fibrinolytic and contact system) further promote this pathway by directly activating complement factors C3a and C5a. Aside from being key molecules in the complement cascade, C3a and C5a are anaphylatoxins and cause an increase in vascular permeability via mast cell degranulation. C5a further activates the lipoxygenase pathway in neutrophils and monocytes, acts as a chemotaxin for leukocytes and monocytes, and promotes neutrophil adhesion to endothelial cells.

13.7.6.5 ACUTE PHASE RESPONSE

In response to acute inflammation, synthesis and secretion of a number of proteins called the acute phase proteins increases in hepatocytes, whereas synthesis of albumin decreases. The primary function of this acute phase response may be to suppress and contain inflammatory responses.[56] IL-6 and IL-1 are the most important cytokines that induce the acute phase response,[90] which typically begins within a few hours of the insult and subsides within 24 to 48 hours,[91] unless the initiating cause persists. In horses, fibrinogen (the most commonly evaluated), haptoglobin, transferrin, ferritin, ceruloplasmin, coagulation factor VIII:C, serum amyloid A protein, C-reactive protein, α_1-acid glycoprotein, and phospholipase A_2 are considered part of the acute phase response.[92] One must consider the effect of acute inflammation on the serum concentration of several coagulation factors when evaluating coagulation profiles. Serum fibrinogen concentration is determined primarily by the acute phase response, although fibrinogen is consumed increasingly on activation of the clotting cascade.

13.7.6.6 HEMODYNAMIC CHANGES, DEVELOPMENT OF SHOCK, AND ORGAN FAILURE

Shock is characterized by a loss of homeostasis attributable to breakdown of hemodynamic control mechanisms, decreases in cardiac output and the effective circulating volume, and inadequate perfusion of vital organs. Shock caused by endotoxemia is classified as distributive shock[93] and is largely initiated by vascular dysfunction in the periphery. Peripheral vascular beds are of major importance for the regulation of local tissue perfusion and affect systemic blood pressure by regulating total peripheral resistance. Normally, vascular smooth muscle tone is regulated by endothelin-1 (vasoconstriction), NO, and prostacyclin (vasodilation) released from vascular endothelial cells.[94] As mentioned before, detrimental effects of NO are attributable to induction of *i*NOS in macrophages and other cell types, rather than endothelial-derived NO. Peripheral vasomotor effects of endotoxin manifest as vasodilation and vasoplegia and are mediated by PGI_2, NO, and mediators such as bradykinin. Widespread vasodilation leads to vascular blood pooling, decentralization of blood flow, decreased venous return, and in effect decreased effective circulating volume and cardiac output.[93] Compensatory responses in the form of an initial hyperdynamic phase include

tachycardia, increased cardiac output and central venous pressure, pulmonary hypertension, peripheral vasoconstriction, and increased peripheral vascular resistance.[93,95,96] The early vasoconstrictive phase corresponds to an increased serum concentration of TXA_2,[17] but additional vasoconstrictors such as arginine vasopressin, angiotensin II, serotonin, endothelin, and norepinephrine likely are implicated in the pathogenesis of shock and organ failure.[56] With progression of disease, the animal enters a stage of decompensated shock and progressive systemic hypotension, which correspond to increased plasma concentrations of prostacyclin, PGE_2 and bradykinin.[17,56] Inadequate blood flow and oxygen delivery to tissues caused by hypotension is confounded by direct myocardial suppression via NO,[93] increased vascular permeability,[17] intravascular microthrombosis, and impaired tissue oxygen extraction[93] and results in progressive metabolic acidosis and inhibition of normal cellular metabolism. 830 831

13.7.7 Clinical Signs and Diagnosis

Quantification of endotoxin in plasma samples is possible. The *Limulus* amebocyte lysate assay is an activity assay based on the endotoxin-sensitive hemolymph coagulation cascade in the horseshoe crab *Limulus polyphemus*. In *Limulus* this reaction is thought to be a defense mechanism against gram-negative infection.[97] Although frequently used as a research tool, the assay is not convenient enough to become a routine clinical test. The clinician therefore must appreciate the primary disease processes associated with a high risk of endotoxemia and rely on clinical signs and clinicopathologic data to achieve a diagnosis. In some cases, endotoxemia may be the first indication of disease or may be the most overt of otherwise subtle clinical manifestations. With colitis or proximal enteritis, for example, one may detect signs of endotoxemia before the development of colic, diarrhea, or gastric reflux, which more specifically indicate the nature of the primary illness. Diseases such as peritonitis or pleuritis, however, may show nonspecific clinical findings including fever, anorexia, and depression. Findings such as neutropenia, which indicate endotoxemia, should urge the clinician to search for a septic process.

In vivo experiments in horses clearly show that many of the clinical signs associated with acute gastrointestinal disease and sepsis are attributable to the activities of lipopolysaccharide and cytokines such as TNF. On administration of sublethal doses of lipopolysaccharide the clinical response can be divided into the early hyperdynamic and the later hypodynamic or shock phases. Clinical signs during the first phase, which begins within 15 to 45 minutes after lipopolysaccharide administration, include anorexia, yawning, sweating, depression, evidence of abdominal discomfort, muscle fasciculation, and recumbency. Heart and respiratory rates increase, and decreased borborygmi suggest ileus. Hyperemia of the mucous membranes and an accelerated capillary refill time indicate the hyperdynamic state.[68] If one administers large amounts of lipopolysaccharide or if exposure is ongoing, depression worsens progressively, anorexia persists, and feces develop diarrheic character. Signs of colic typically abate after the initial stage. Fever develops as a result of direct action of TNF on the thermoregulatory center and IL-1-induced local production of PGE_2 in or near the hypothalamus.[98,99] Because of compromised peripheral perfusion, mucous membrane color changes to brick red or purple, a dark "toxic" line appears, and capillary refill time is prolonged.[68] Inadequate peripheral perfusion and compromised organ function finally characterize the hypodynamic shock phase. Body temperature may become subnormal and the skin, especially on extremities, is cool to the touch. The arterial pulse weakens and venous fill is decreased. Vascular endothelial damage and increased capillary permeability result in a muddy mucous membrane color and diffuse scleral reddening.

Hemostatic abnormalities can manifest in the form of thrombosis, such as of the jugular vein, or increased bleeding tendency with mucosal petechiation or ecchymoses and prolonged bleeding from venipuncture sites.[74]

Bleeding also may occur in spontaneous epistaxis or prolonged hemorrhage after nasogastric intubation.[17] Additional clinical signs typically reflect the development of organ failure. Renal failure and laminitis appear to be common complications of endotoxemia in horses. Renal failure results from ischemic cortical necrosis and acute tubular necrosis caused by coagulopathy-induced afferent arteriolar obstruction. Clinical signs may include oliguria, anuria, or hematuria caused by renal infarction. Laminitis may lead to lameness, increased digital arterial pulsation, increased warmth of the hoof wall, and sensitivity to hoof tester pressure. Other signs of organ failure include icterus, anorexia and depression caused by liver failure,[74] tachypnea and dyspnea caused by pulmonary failure, colic and bleeding caused by ischemia-induced gastrointestinal ulceration and abnormal motility patterns,[17] and persistent tachycardia or cardiac arrhythmia in cases of cardiac failure. In pregnant mares, fetal death and abortion can occur because of increased production of $PGF_{2\alpha}$ and decreased serum progesterone concentrations.[100,101]

13.7.8 Alterations in the Hemogram and Serum Biochemistry Profile

Alterations in the hemogram and serum biochemical profile are nonspecific and mainly reflect the underlying 831
disease process and the occurrence of organ failure. Leukopenia caused by neutropenia may be the most specific 832
indicator of acute bacterial sepsis or endotoxemia.[68] In prolonged cases, an increased proportion of immature neutrophil forms (bands) and toxic changes are observable. Toxic changes resulting from neutrophil activation include vacuolation, cytoplasmic granulation, basophilic cytoplasm, and Döhle's bodies. Because neutropenia occurs early in the development of endotoxemia, it also may be a useful parameter for monitoring horses at risk.[68] On recovery, neutropenia typically is followed by a pronounced rebound neutrophilia.

An elevated hematocrit and total serum protein concentration are evidence of dehydration; however, splenic contraction caused by increased sympathetic stimulation and protein losses also influence these parameters. A normal or only slightly decreased serum protein and albumin concentration in the face of an elevated hematocrit and clinical signs of dehydration should alert the clinician to the possibility of protein loss. Hypoproteinemia and hypoalbuminemia can occur because of loss via the gastrointestinal or urinary tract or with pleural or peritoneal cavity effusion. Increased vascular permeability and edema formation contribute to hypoproteinemia.

Serum electrolyte abnormalities primarily depend on the nature and duration of underlying disease processes and need to be evaluated individually. Common sources of electrolyte loss are gastrointestinal secretions, urine, and sweat; however, severe effusion into body cavities may contribute. In anorexic patients, lack of dietary intake is a confounding factor that warrants consideration. In human patients, gram-negative sepsis frequently is associated with hypocalcemia, more specifically a decrease in serum ionized calcium concentration. Endotoxin is thought to be a causative factor, and proposed mechanisms include acquired parathyroid gland insufficiency, dietary vitamin D deficiency, impaired calcium mobilization, and renal 1α-hydroxylase insufficiency leading to decreased 1,25-hydroxylation of vitamin D. Hypocalcemia in septic human patients was found to be associated with hypotension and poor outcome.[102] In horses with surgically managed gastrointestinal disease, decreased serum ionized calcium concentration was a common finding and was most severe in patients with strangulating or nonstrangulating infarctions. In some horses, ionized calcium concentration decreased further throughout surgery. Treatment with calcium gluconate resulted in normalization of serum ionized calcium concentrations in all cases.[103]

Septic neonatal patients are frequently hypoglycemic. Aside from decreased oral intake and generally increased metabolism, glucose use by the infecting bacteria, inhibition of gluconeogenesis by endotoxin, and insulin-like activity produced by macrophages are responsible for hypoglycemia.[17] Interestingly, experimental endotoxin

administration results in transient hyperglycemia in adult horses,[95] whereas profound hypoglycemia occurs in foals.[104]

One should evaluate coagulation parameters if coagulopathy is suspected. The most significant changes can be expected with severe inflammatory disease such as colitis,[72,73] devitalized intestine as with strangulating obstruction,[73,105] and with increased duration of disease. In 30 horses with acute gastrointestinal disease, coagulation profiles were considered normal in only 2 horses.[72] Although coagulation times may be shortened during the procoagulant state, commonly observed abnormalities with developing DIC include an increased concentration of FDPs and soluble fibrin monomer, prolonged prothrombin time indicative of factor VII consumption, prolonged activated partial thromboplastin time indicative of factor VIII:C and IX consumption, prolonged thrombin time, decreased AT III activity, thrombocytopenia, and decreased protein C and plasminogen activities. Fibrinogen concentration frequently increases and reflects the acute phase response rather than coagulation abnormalities.[79] Some clinicians make a diagnosis of DIC if three or more coagulation parameters (specifically AT III, FDPs, platelet count, prothrombin time, and activated partial thromboplastin time) are abnormal,[105] whereas others require overt clinical signs of hemorrhage and concomitant thrombosis in addition to classic laboratory findings.[73] The prognostic value of coagulation parameters has been evaluated.[16,73,89] Overall, persistence or worsening of abnormalities in the face of treatment appears to be more indicative of poor outcome than alterations in any specific parameter. In one study, decreased serum AT III concentration was the parameter most commonly associated with fatal outcome in mature horses with colic.[72]

One should further evaluate the serum biochemical profile regarding compromise or failure of specific organ systems. Increases in serum creatinine and urea nitrogen concentration can have prerenal, renal, or postrenal causes. In cases of endotoxemia and sepsis, prerenal azotemia caused by dehydration and decreased renal blood flow and renal azotemia caused by organ failure are most likely to occur. One can use urine specific gravity and the response to fluid therapy to differentiate renal from prerenal causes of azotemia. Although ideally one should perform urinalysis before initiating fluid therapy, one should never delay treatment to obtain a sample and instead should use the first available urine sample. With prerenal azotemia, urine specific gravity is increased, urinalysis is normal in other respects, and azotemia resolves with adequate fluid therapy. Azotemia in the face of normal or decreased urine specific gravity, however, indicates compromised renal function. Depending on the 832
extent of renal damage, proteinuria and hematuria also may be present. Bacteriuria and an elevated urine 833
leukocyte count may occur if urinary tract infection is the underlying cause for the development of endotoxemia. In these cases, urine culture and sensitivity testing are indicated to aid appropriate antimicrobial therapy.

Increased serum activity of liver enzymes (aspartate aminotransferase, γ-glutamyltransferase, sorbitol dehydrogenase, alkaline phosphatase) are common in endotoxemic patients; however, liver failure caused by endotoxemia is rare. Sorbitol dehydrogenase is the most liver-specific of the enzymes and a sensitive indicator of acute hepatocellular necrosis; however, sorbitol is unstable and routine assays may not be available. One should evaluate liver enzymes and function tests (serum indirect and direct bilirubin concentration, serum bile acids and blood ammonia) in cases of prolonged and profound depression to rule out hepatoencephalopathy.

One should evaluate arterial blood gases in patients with primary respiratory disease or with clinical evidence of respiratory failure and in profoundly depressed, recumbent patients, especially neonates. Hypoxemia observed in response to endotoxin infusion is thought to be caused by an increase in ventilation-perfusion mismatch rather than pulmonary edema as occurs in human patients with acute respiratory distress syndrome. The lung is not a major shock organ in horses; however, pulmonary edema may occur in patients with associated sepsis or complications such as DIC.[106]

13.7.9 Management

The ideal treatment for endotoxemia is prevention. If one possibly can recognize and closely monitor patients at risk, one can provide treatment proactively and may reverse the effects of endotoxin before the inflammatory response has developed a dynamic of its own. Unfortunately, endotoxemia can develop rapidly, and horses are exquisitely sensitive to the effects of endotoxin; therefore, many equine patients are not evaluated until reaching more severe stages of endotoxemia or shock. Prognosis and patient outcome then frequently depend on the severity of complications associated with endotoxemia.[17]

Treatment of endotoxemia involves multiple aspects, and the following strategies have been proposed[107]:

- Inhibition of endotoxin release into the circulation
- Scavenging of lipopolysaccharide molecules to prevent direct effects and interaction with inflammatory cells
- Inhibition of cellular activation by lipopolysaccharide
- Inhibition of mediator synthesis
- Interference with the effects of inflammatory mediators
- General supportive care

In addition, complications such as renal failure, one also must address liver failure, cardiac failure, laminitis, and abortion in pregnant mares.

When evaluating reports concerning the efficacy of any one treatment, one should keep in mind differences in underlying disease processes and the complexity of the inflammatory cascade. A “one for all” treatment most likely will not be found, and similarly, any one treatment can only address one or few pathophysiologic aspects of endotoxemia. Understanding the rationale for different treatment strategies is important to be able to tailor treatment to the needs of the patient.

13.7.9.1 INHIBITION OF ENDOTOXIN RELEASE INTO THE CIRCULATION

Inhibition of endotoxin release requires identification and removal of its source. Therefore whenever endotoxemia is evident, the clinician should strive to reach a diagnosis of the underlying disease and ascertain whether ischemic or inflamed bowel or a gram-negative septic process is present. Aside from history, physical examination, and routine laboratory tests, evaluation may include exploratory laparotomy in colic patients, roentgenologic and ultrasonographic evaluation of the pleural and peritoneal cavity and organs, ultrasonographic evaluation of umbilical remnants in neonatal foals, evaluation of passive transfer and calculation of a sepsis score in foals, and repeated culturing of blood or other specimens. If one suspects an infectious process, one should pursue identification of the responsible microorganisms and their antimicrobial sensitivity spectrum; however, one should not delay treatment to obtain culture results. Specimen containers with removal devices for antimicrobials are available and are useful in cases for which one has initiated treatment before specimen collection. Once one reaches a diagnosis, one must take appropriate measures to correct the primary disease process. Examples are removal of devitalized sections of bowel or infected umbilical remnants, drainage of infected pleural or peritoneal fluid, and gastric lavage followed by

administration of mineral oil and/or activated charcoal in cases of grain overload to prevent further absorption of endotoxin. One must address any septic process with appropriate antimicrobial therapy. Initially, broad-spectrum coverage of the most likely organisms is recommended; one then should specify therapy according to results of culture and sensitivity testing. Sepsis in foals is caused predominantly by gram-negative organisms, of which *E. coli, Actinobacillus* spp., *Klebsiella* spp., *Salmonella* spp. and *Pasteurella* spp. frequently are identified.[108] The reader is referred to other texts for review of general principles of antimicrobial therapy. Regarding endotoxemia specifically, antimicrobial therapy has been suggested to 833
increase the amount of circulating endotoxin by inducing endotoxin release on cell death of gram-negative 834
bacteria. A recent in vitro study compared endotoxin release and inflammatory mediator activity between antimicrobials commonly used to treat *E. coli* septicemia in foals and specifically evaluated amikacin, ampicillin, amikacin plus ampicillin, ceftiofur, and imipenem. Although these antimicrobials showed no difference in the ability to kill bacteria, amikacin and the amikacin/ampicillin combination resulted in the lowest and ceftiofur in the greatest release of endotoxin. Endotoxin release appeared to be dose-dependent in that lesser amounts were released at higher antimicrobial concentrations.[109] Based on these results and clinical experience, combining antimicrobial therapy with endotoxin-binding agents such as polymyxin B may be beneficial, especially when using β-lactam antimicrobials.

Antimicrobials frequently are given perioperatively to colic patients to lower the risk of peritonitis, incisional infection, and generalized sepsis and endotoxemia. Because antimicrobial therapy has been implicated in the development of colitis, the duration of treatment should be minimal. Unless evidence of sepsis, such as fever or changes in the leukogram, is present, perioperative administration of antimicrobials should not exceed a 24 to 48 hours. Conversely, antimicrobial therapy frequently is used in cases of infectious colitis to treat the inciting cause and to prevent sepsis from translocation of bacteria.

13.7.9.2 SCAVENGING OF LIPOPOLYSACCHARIDE MOLECULES

Endotoxin typically has a short plasma half-life and is removed rapidly by mononuclear phagocytes or neutralized by binding to serum proteins and lipoproteins. Many conditions responsible for the development of endotoxemia in horses, however, are associated with an ongoing release of endotoxin. Examples include severe gastrointestinal inflammation as in proximal enteritis or colitis, grain overload, or uncontrolled sepsis. Therapy directed against endotoxin itself may be able to interrupt the continuous activation of the inflammatory cascade in these cases. Further benefits of antiendotoxin treatment may be derived if large amounts of endotoxin have been released before the inciting cause can be addressed.

13.7.9.2.1 Immunotherapy

An important consideration regarding the efficacy of immunotherapy is the region of the lipopolysaccharide molecule against which antibodies are raised. The O-chain of lipopolysaccharide acts as a potent antigen on infection with gram-negative bacteria[6]; however, antibodies directed against the O-chain are serotype specific and cannot afford significant cross-protection against heterologous bacterial strains. The core and lipid A region, both of which show a much higher degree of homology between lipopolysaccharide derived from different bacterial strains, offer a more promising target for immunotherapy. Active immunization against endotoxin has been reported for horses. Vaccination with a bacterin/toxoid vaccine prepared from rough mutants of *Salmonella typhimurium* or *S. enteritidis* protected horses against homologous and heterologous endotoxin challenge[110,111] and carbohydrate overload.[111] Despite these encouraging results and the current availability of a vaccine for use in horses (Endovac-Equi, Immvac Inc., Columbus, Missouri), active immunization against endotoxin does not appear to be a common practice. In comparison,

passive immunization with antilipopolysaccharide antibodies is used widely. Rough bacterial mutants, most commonly J5 of *E. coli* O111:B4 and *S. minnesota* Re595, are used to immunize donor horses and subsequently prepare serum or plasma products. Proposed mechanisms of action after binding of the antibodies to lipopolysaccharide include steric blockade of lipid A interaction with cellular receptors and enhanced bacterial clearance by opsonization.[112–114] Studies concerning the efficacy of antibody administration in equine patients vary in their results. Beneficial effects have been described in experimental models of endotoxemia, acute gastrointestinal disease, and neonates with sepsis,[111,115–117] whereas in other studies, antibodies failed to protect foals and horses against endotoxin effects.[118–120] Furthermore, administration of a *S. typhimurium* antiserum to foals was associated with an increased respiratory rate and higher serum activities of IL-6 and TNF.[118]

Various equine serum and plasma products are currently commercially available. An antiserum raised against the lipopolysaccharide-core of *S. typhimurium* (Endoserum) is available for administration to endotoxemic horses at a recommended dose of 1.5 ml/kg body mass. Diluting the serum ten- to twentyfold in crystalloid intravenous solutions, administering it slowly over 1 to 2 hours, and monitoring the patient for adverse reactions is advisable. Although the product is marketed for use in foals with failure of passive transfer, adverse effects have been reported,[118] and one should use caution when administering it to neonates. Plasma from donors inoculated with J5 *(E. coli)* and *S. typhimurium* (Re mutant) is available under a restricted license (Polymune-J, Vet Dynamics, Inc., San Louis Obispo, California). The manufacturer recommends administration of at least 1 to 2 L in cases of endotoxemia. In addition, hyperimmune plasma, which has a guaranteed minimum immunoglobulin G content but does not contain specific antiendotoxin antibodies (Hi-Gamm Equi, Lake Immunogenics, Inc., Ontario, New York; Polymune and Polymune-Plus, Vet Dynamics, Inc.), is marketed for treatment of failure of passive transfer, 834
and many clinicians use it to treat endotoxemia and sepsis. In addition to antibodies and protein, plasma 835
contains active constituents such as complement components, fibronectin, clotting factors, and AT III[116] and therefore may be particularly useful in patients with endotoxemia-induced coagulopathy. Volumes of 2 to 10 ml/kg body mass of hyperimmune plasma have been recommended for use in endotoxemic patients.[56,121]

13.7.9.2.2 Polymyxin B

Polymyxin B is a cationic polypeptide antibiotic that binds to the anionic lipid A portion of lipopolysaccharide and neutralizes its endotoxin capacity.[122] At dosages required for antimicrobial activity, polymyxin B carries the risk of respiratory paralysis and ototoxic, nephrotoxic, and neurotoxic side effects; however, a much lower dose is required for endotoxin-binding activity. The effects of polymyxin B in horses have been evaluated in different experimental models.[118,122,123] In an in vivo study in foals, treatment with polymyxin B at a dosage of 6000 U/kg body mass before infusion with *S. typhimurium* lipopolysaccharide resulted in significantly less severe elevations of body temperature, respiratory rate, and serum activities of TNF and IL-6 compared with untreated controls.[118] Similarly, polymyxin B treatment of adult horses given endotoxin significantly ameliorated clinical signs and decreased plasma TNF activity.[124] In the latter study, benefits of treatment were also evident at lower dosages of polymyxin B (1000 and 5000 U/kg body mass) and administration of polymyxin B 1 hour after the start of endotoxin infusion. Conversely, polymyxin B failed to ameliorate clinical signs of endotoxemia or prevent the development of coagulopathy, acidosis, lameness, and shock in experimental carbohydrate overload.[125] Side effects suggestive of neurotoxicity appeared after repeated administration of 5 mg/kg body mass (36,000 U/kg) and

in milder form, 2.5 mg/kg body mass (18,000 U/kg) polymyxin B. Nephrotoxicity was not observed. Currently, use of polymyxin B in equine patients is recommended at dosages of 1000 to 5000 U/kg body mass every 8 to 12 hours.[126] One should initiate treatment as early in the disease process as possible, because the beneficial effects of lipopolysaccharide scavenging are limited to the first 24 to 48 hours after the onset of endotoxemia, before tolerance develops. Side effects in the form of neuromuscular blockade and apnea, which necessitate slow infusion of the drug in human patients, have not been observed in horses. One therefore can administer the entire dose as a slow bolus. If one uses polymyxin B in horses with hypovolemia, dehydration, or azotemia, one should attempt to improve peripheral tissue perfusion, minimize the polymyxin B dose, and closely monitor patients for nephrotoxicity. Close monitoring is also important if one administers medications such as aminoglycoside antibiotics, which share a similar spectrum of potential side effects, concurrently. Azotemic neonates have been reported to be more susceptible to the nephrotoxic effects of polymyxin B than adult horses.[124]

In an attempt to decrease the risk for adverse effects while preserving lipopolysaccharide-neutralizing ability, a conjugate of polymyxin B with dextran has been developed.[127] In conjugated form, polymyxin B is prevented from extravasation into tissues, where it exerts toxic effects by interaction with cell membranes. In addition, conjugation increases the residence time of polymyxin B in the circulation and therefore should prolong the antiendotoxic effect. The polymyxin B–dextran combination was evaluated at a total dose of 5 mg/kg body mass of polymyxin B in 6.6 g/kg body mass dextran given 15 minutes before administration of endotoxin in horses.[128] Treatment was found to block the development of tachycardia, tachypnea, fever, and neutropenia completely and to prevent increases in serum concentrations of TNF, IL-6, TXB_2 (a TXA_2 metabolite), and the prostacyclin metabolite 6-keto-PGF_{1a}. Although mild adverse effects in the form of tachypnea, sweating, and increased systolic blood pressure were observed, these were transient and could be prevented by pretreatment with ketoprofen. The polymyxin B–dextran combination is not commercially available at this time.

13.7.9.2.3 Natural Endotoxin-Binding Substances

Natural endotoxin-binding proteins such as LBP, lipoproteins, and sCD14 have been evaluated experimentally. Results of these studies are controversial, and detrimental effects occurred in some cases. [129] A protein receiving much attention regarding potential therapeutic efficacy is the bactericidal permeability-increasing protein (BPI). This protein is structurally similar to LBP but is expressed exclusively in myeloid precursors of polymorphonuclear leukocytes.[130] BPI is stored in primary granules of mature neutrophils and during inflammation is expressed on their cell membranes and secreted into the extracellular environment.[131] BPI has an even higher affinity for lipopolysaccharide than LBP[132] and shows antibacterial activity specific for gram-negative bacteria.[65] Binding of BPI to the gram-negative bacterial membrane results in growth arrest and is an important factor in the antibacterial activity of intact neutrophils. Furthermore, BPI binding disrupts normal membrane organization and makes bacteria more susceptible to hydrophobic substances, including antimicrobials.[133] Experimentally, recombinant BPI has been shown to protect against the toxic and lethal effects of isolated lipopolysaccharide and intact gram-negative bacteria, and clinical trials in human patients show promising results concerning its therapeutic use.[134] The biology and potential use of BPI in horses has not been evaluated. 835

13.7.9.3 INHIBITION OF CELLULAR ACTIVATION BY LIPOPOLYSACCHARIDE

Treatments aimed at inhibiting lipopolysaccharide interaction with cells or turning off intracellular signaling pathways are under investigation. Nontoxic lipopolysaccharide or lipid A structures can act as endotoxin antagonists, if they competitively inhibit binding to LBP or cellular receptors or inhibit cellular activation by other mechanisms. Of the potential antagonists that have been evaluated experimentally, lipopolysaccharide and lipid A from the phototrophic bacterium *Rhodobacter sphaeroides,* and a synthetic compound (E5531) the structure of which is based on *R. sphaeroides* lipopolysaccharide, have been most promising.[135–139] Unfortunately, species differences exist regarding cellular response to these structures, and *R. sphaeroides* lipopolysaccharide acts as a potent inducer of cytokine expression in equine cells.[140] Based on results of receptor transfection studies in other species,[141,142] TLR4 is likely responsible for this phenotypic variation. Additional compounds including lipopolysaccharide derived from nitrogen-fixing plant bacteria of the species *Rhizobium* are being evaluated to reveal further insight into structural requirements for endotoxin antagonists in horses.

13.7.9.4 INHIBITION OF MEDIATOR SYNTHESIS

13.7.9.4.1 Nonsteroidal Antiinflammatory Drugs

Nonsteroidal antiinflammatory drugs (NSAIDs) are probably the most commonly used drugs to treat endotoxemia. The rationale for their use is inhibition of prostaglandin endoperoxide H synthase, that is, COX, and thereby inhibition of prostanoid production (see Figure 13.7-5). Additional beneficial effects may include scavenging of oxygen-derived free radicals and iron chelation; however, side effects may occur at dosages required to achieve these effects.[143] Prostanoids have been identified as important mediators in the inflammatory response in a number of studies, and inhibition of their synthesis is associated with beneficial effects. Two COX isoforms are recognized: constitutively expressed COX-1 and inducible COX-2. Upregulation of COX-2 expression results from various proinflammatory stimuli, including lipopolysaccharide, TNF-α, and IL-1.[144] Constitutively expressed COX products are likely important for maintenance of homeostasis, whereas increased production of prostanoids by COX-2 is thought to be responsible for detrimental effects during inflammation and shock. Research has focused on the development of selective COX-2 inhibitors; however, none of these products are currently available for use in horses. In horses the most commonly used NSAID to treat endotoxemia is flunixin meglumine. Beneficial effects of flunixin meglumine have been described in experimental models of endotoxemia[145–147] and in clinical cases. In equine colic patients, treatment with flunixin meglumine before exploratory surgery resulted in reduced plasma concentrations of TXB_2 and PGE_2 and had a favorable effect on cardiovascular parameters.[148] Flunixin meglumine was shown further to maintain cardiac output and systemic arterial blood pressure, improve blood flow to vital organs, reduce pulmonary endothelial damage, and improve survival on endotoxin challenge.[149–152]

NSAID use in horses carries the risk of side effects, most importantly the development of gastrointestinal ulceration and renal papillary necrosis (renal crest necrosis). In a study comparing the side effects of flunixin meglumine (1.1 mg/kg body mass), phenylbutazone (4.4 mg/kg body mass), and ketoprofen (2.2 mg/kg body mass) given 3 times daily for 12 days, lesions of the gastric glandular mucosa occurred most commonly. Phenylbutazone resulted in the most severe side effects, which included small intestinal edema,

erosions, and ulcers in the large colon and decreased serum albumin concentration. Renal crest necrosis occurred more frequently in horses treated with phenylbutazone but also occurred with flunixin meglumine treatment.[153] Despite the higher risk of side effects, use of phenylbutazone has been suggested for certain cases. In colic patients, phenylbutazone may provide analgesia and ameliorate endotoxin-induced ileus without masking cardiovascular effects of endotoxin, which are used to determine the necessity of surgical exploration.[154] For similar reasons and to minimize side effects a reduced dose of flunixin meglumine (0.25 mg/kg body mass) has been suggested and is used widely in horses.[155] At this dosage, flunixin meglumine was shown to inhibit eicosanoid synthesis efficiently in an in vivo model of endotoxemia.[156] Reduction of clinical signs, however, was dose dependent, and therefore one should choose the appropriate dose based on the circumstances of each case.

Ketoprofen has been suggested to have superior effects because of a proposed dual inhibitory effect on COX and lipoxygenase and may carry a decreased risk of side effects compared with flunixin meglumine and phenylbutazone. A comparison of cytokine and eicosanoid production by lipopolysaccharide-stimulated isolated monocytes in vitro, however, showed no significant difference between horses pretreated with flunixin meglumine (1.1 mg/kg body mass) or ketoprofen (2.2 mg/kg body mass), respectively.[157]

Eltenac has been evaluated in an experimental endotoxemia model in horses.[158] Given 15 minutes before lipopolysaccharide infusion, eltenac at a dose of 0.5 mg/kg protected against changes in clinical, hemodynamic, and hematologic parameters and blunted the lipopolysaccharide-induced rise in plasma cytokine concentrations in comparison with controls. Some parameters, however, including heart rate, 836
leukocyte count, lactate concentration, and plasma TNF activity, were not improved. 837

Ibuprofen may have beneficial effects superior to the other NSAIDs, because it may be possible to achieve tissue concentrations safely that allow iron chelation to occur. According to a study in healthy foals, dosages of ibuprofen up to 25 mg/kg every 8 hours can be given safely for up to 6 days.[143]

13.7.9.4.2 Corticosteroids

The use of corticosteroids for antiinflammatory therapy in sepsis and endotoxemia has been controversial in human and equine patients, and beneficial effects superior to the ones achieved by NSAIDs have not been demonstrated consistently overall. Corticosteroids inhibit the activity of phospholipase A_2 and the release of arachidonic acid from cell membrane phospholipids, as well as the production of TNF, IL-1, and IL-6 in response to a lipopolysaccharide stimulus. Experimentally, beneficial effects of dexamethasone in equine endotoxemia have been demonstrated.[159,160] To inhibit TNF production by equine peritoneal macrophages, however, the required concentration of dexamethasone was high and corresponded to an in vivo dosage (approximately 3 mg/kg body mass) greatly exceeding current recommendations.[159] Although single doses of corticosteroids are unlikely to carry a disproportionate risk of side effects, one should consider the suggested association of laminitis with corticosteroid use in horses. In cases of sepsis, further immunosuppressive effects could be detrimental.

In human patients with certain types of septic shock, dysfunction of the hypothalamic-pituitary-adrenal axis has been recognized and successfully treated with hydrocortisone replacement therapy.[161] Use of corticosteroids for this indication has not been evaluated in horses.

13.7.9.4.3

Pentoxifylline

Pentoxifylline, a methylxanthine derivative and phosphodiesterase inhibitor, has been suggested for use in endotoxemia because of its effects on neutrophil function and its ability to inhibit the production of various cytokines, interferons, and thromboplastin. Decreased production of TNF, IL-6, TXB_2, and thromboplastin in response to endotoxin was shown in an equine ex vivo model.[162] In horses given endotoxin followed by treatment with pentoxifylline (7.5 mg/kg body mass followed by continuous infusion of 3 mg/kg/hr for 3 hours), however, only minimal beneficial effects were observed.[163] Treatment significantly improved body temperature, respiratory rate, and whole blood recalcification time, but no effect was observed regarding heart rate, blood pressure, leukocyte count, plasma fibrinogen concentration, and serum cytokine concentrations. The conclusion was that benefits of treatment with pentoxifylline might be restricted to administration of high bolus doses or continuous infusion early in the pathophysiologic process. In an in vivo endotoxemia model in horses, combination of pentoxifylline (8 mg/kg body mass) and flunixin meglumine (1.1 mg/kg body mass) was found to have greater benefit than each treatment on its own.[164] The currently recommended dosage for oral administration of pentoxifylline is 8 mg/kg every 8 hours. Because of its rheologic properties, that is, the ability to increase erythrocyte deformability and microvascular blood flow, pentoxifylline may be particularly useful in endotoxemic patients showing evidence of laminitis. An intravenous preparation of pentoxifylline is not commercially available.

13.7.9.4.4

Antioxidants

Dimethyl sulfoxide (DMSO) is used frequently in an attempt to scavenge oxygen-derived radicals. The treatment may be most appropriate in cases of ischemia-induced intestinal damage and associated reperfusion injury. However, DMSO failed to show beneficial effects in an experimental model of intestinal ischemia when administered on reperfusion of the ischemic intestine.[165] DMSO at the commonly used dose of 1 g/kg body mass was shown to increase mucosal loss after ischemia and reperfusion of the large colon,[166] and hence a reduced dose of 0.1 g/kg body mass has been proposed for cases of intestinal ischemia. For intravenous administration, DMSO needs to be diluted in polyionic solutions to a concentration not exceeding 10%. Oral administration of a 10% to 20% solution via nasogastric intubation is also possible. Aside from DMSO the xanthine oxidase inhibitor allopurinol has been suggested as a treatment to prevent oxygen radical–induced tissue damage. During periods of ischemia, tissue xanthine dehydrogenase is converted to xanthine oxidase, which on reperfusion catalyzes the generation of superoxide radicals.[167,168] Evaluation in horses showed beneficial effects of 5 mg allopurinol per kilogram body mass administered 12 hours before endotoxin challenge.[169] In another study, mucosal damage attributable to oxygen-derived free radicals was not attenuated by allopurinol in an experimental ischemia-reperfusion model.[166]

13.7.9.4.5

Lidocaine

Lidocaine given intravenously has been suggested as an antiinflammatory, analgesic, and prokinetic agent, and some clinicians use it to treat colic and laminitis in horses. In an experimental endotoxemia model in rabbits, lidocaine was found to inhibit hemodynamic and cytokine responses to endotoxin profoundly if given immediately following lipopolysaccharide infusion.[170] Use of lidocaine therefore may have additional merit in endotoxemic patients. A common regimen for lidocaine use in horses is administration 837

of an initial bolus (1.3 mg/kg body mass) followed by continuous infusion at a rate of 0.05 mg/kg/min. One should monitor patients for toxic neurologic effects associated with a lidocaine overdose. 838

13.7.9.4.6

ω-3 Fatty Acids

High concentrations of ω-3 fatty acids can alter the phospholipid composition of cellular membranes toward a decreased ratio of ω-6 to ω-3 and thereby can affect membrane functions such as phagocytosis, receptor binding, and activities of membrane-bound enzymes.[68] Most importantly for the treatment of endotoxemia, ω-3 fatty acid incorporation into cell membranes decreases the availability of arachidonic acid (an ω-6 fatty acid) for eicosanoid synthesis[171] and provides alternative substrates. Metabolism of ω-3 fatty acids via the COX and lipoxygenase pathway leads to the production of 3-series prostaglandins and 5-series leukotrienes, which have less biologic activity than their 2-series and 4-series counterparts derived from arachidonic acid. Aside from these mechanisms, ω-3 fatty acids prevent lipopolysaccharide-induced upregulation of CD14 in monocytic cells and therefore may be able to block transmembrane signaling of lipopolysaccharide.[172] Cells from horses given linseed oil (high in ω-3 fatty acids) for 8 weeks before blood collection showed significantly decreased expression of procoagulant activity, TXB_2, and TNF in response to lipopolysaccharide stimulation.[173,174] In an in vivo experimental model of endotoxemia in horses, treatment resulted in prolonged activated partial thromboplastin time and whole blood recalcification time, suggesting an anticoagulant effect; however, a significant beneficial effect on clinical response and serum eicosanoid concentrations was not observed.[175] Because dietary addition of ω-3 fatty acids requires several weeks of treatment, intravenous infusion was evaluated and shown to alter the composition of cell membrane phospholipids rapidly.[176] Further evaluation of this treatment for use in horses is necessary before dosage recommendations can be made.

13.7.9.5

INTERFERENCE WITH THE EFFECTS OF SPECIFIC INFLAMMATORY MEDIATORS

13.7.9.5.1

Antibodies Directed Against Tumor Necrosis Factor

Monoclonal and polyclonal antibodies against equine TNF have been evaluated.[177–179] Administration of a monoclonal antibody preparation before lipopolysaccharide infusion resulted in significantly reduced plasma TNF-activity, improved clinical abnormality scores, lower heart rate, and higher leukocyte count compared with controls.[178] Furthermore, plasma concentrations of lactate and 6-keto-PGF_{1a} were reduced significantly, whereas TXA_2 production was not affected.[177] In another study,[179] administration of a rabbit polyclonal antibody against recombinant human TNF was unable to improve clinical and hematologic parameters when given shortly (15 minutes) after lipopolysaccharide infusion, although inhibition of TNF activity was present in vitro.[179,180] Findings in horses are in agreement with studies in other species and suggest that beneficial effects of TNF inhibition may be limited to administration before lipopolysaccharide exposure. Widespread clinical use therefore is unlikely to become feasible. Clinical trials in human patients have not shown significant benefits of TNF antibody treatment.[181,182]

13.7.9.5.2

Platelet-Activating Factor Receptor Antagonists

The effects of selective PAF receptor antagonists have been evaluated. PAF is implicated in the development of systemic hypotension,[183] lipopolysaccharide-induced platelet aggregation,[184] ileus,[185] and

increased vascular permeability[186] and may mediate recruitment of leukocytes to inflamed tissues.[187,188] A study in horses using the PAF receptor antagonist SRI 63-441 before lipopolysaccharide infusion showed significant decreases in heart rate and shorter elevation of lactate concentrations in response to the treatment. Although not statistically significant, additional beneficial effects included delayed onset of fever, a shortened period of neutropenia, and reduced maximal platelet aggregation.[189]

13.7.9.6 SUPPORTIVE CARE

13.7.9.6.1 Fluid Therapy and Cardiovascular Support

Whenever possible, the clinician should correct volume and electrolyte deficits, or at least improve them, before anesthetizing a patient for a surgical procedure. For initial resuscitation, polyionic solutions such as lactated Ringer's solution given at rates of 10 to 20 ml/kg/hr are appropriate. Patients with severe hypovolemia and shock may require higher fluid volumes. A viable alternative to large-volume resuscitation with isotonic fluids is the use of small volumes of hypertonic solutions, which transiently raise plasma osmolality, thereby causing a fluid shift from the interstitial space into the vasculature and rapidly restoring circulating volume. Hypertonic saline solution (7.5% sodium chloride) is the most commonly used hypertonic solution and has been shown to have beneficial effects in endotoxemic horses.[190] A dose of 4 ml/kg is recommended, which one should give as a bolus infusion over 10 to 15 minutes, followed by administration of an isotonic solution to restore total body fluid volume. One should use hypertonic saline with caution in patients with sodium and/or chloride derangements and should monitor serum electrolyte concentrations in the case of repeated administration. Improvement of the cardiovascular status in response to fluid therapy is indicated by normalization of heart rate, mucous membrane color, and capillary refill 838
time. Failure of urination to occur despite appropriate fluid resuscitation should result in critical evaluation 839
of renal function.

Once one has stabilized the patient, one should choose a maintenance fluid rate to maintain adequate hydration and plasma volume. For adult horses, the maintenance fluid rate is approximately 2 ml/kg/hr, whereas neonatal foals that are not nursing may require larger volumes (4 ml/kg/hr). One should monitor fluid administration carefully in endotoxemic patients, because lowered plasma oncotic pressure caused by hypoproteinemia along with an increased vascular permeability increase the risk of tissue edema formation. Furthermore, a rapid increase in total body fluid volume may be detrimental in patients with compromised cardiac and peripheral vasomotor function and may increase the severity of vascular pooling in peripheral organs. In these patients, hypertonic saline or colloids may be more appropriate means of stabilization than large volumes of crystalloid solutions.

Plasma is an ideal colloid and should be administered to maintain a serum total protein concentration above 4.2 g/dl.[121] To raise plasma protein concentration and colloid osmotic pressure significantly, however, horses often require large volumes of plasma (7 to 10 L or more in a 450-kg horse), and one should consider alternative colloids. Furthermore, high-molecular-weight polymers are thought to provide superior oncotic effects in cases of sepsis and endotoxemia, when vascular permeability is increased. Hetastarch, or hydroxyethyl starch, (Hespan) is commercially available as a 6% solution in 0.9% sodium chloride. Hetastarch molecules have very high molecular weight, and degradation must occur before renal excretion.[191] These properties result in a longer plasma half-life and prolonged oncotic effects compared with other colloids; persistence of the oncotic effect for 24 hours was found in hypoproteinemic horses.[192] A dosage of 5 to 15 ml/kg given by slow intravenous infusion along with an equal or greater volume of crystalloid fluids

is recommended.[191,193] In human patients, prolonged activated partial thromboplastin time, decreased factor VIII activity, and decreased serum fibrinogen concentration have been described in association with hetastarch use.[194] In the limited number of equine studies, bleeding times were not affected[195,196]; however, one should monitor patients treated with hetastarch for coagulopathy.

One should base correction of serum electrolyte concentrations on the results of laboratory evaluation. Ideally, one should evaluate serum electrolyte concentrations of patients receiving fluid therapy daily. One should take ongoing losses and lack of dietary intake into account, especially when serum concentrations, as in the case of potassium, poorly reflect total body electrolyte stores. Potassium supplementation is recommended in patients experiencing prolonged (greater than 48 hours) periods of anorexia. One can add calcium in the form of calcium gluconate, which is available as a 23% solution. Based on a study in healthy horses, rates of administration for calcium gluconate in the range of 0.1 to 0.4 mg/kg/min are recommended, [197] and as a guideline, one should administer 0.5 to 1 ml/kg body mass per day of a 23% solution. One can add potassium in the form of potassiu m chloride or potassium gluconate to intravenous solutions at a dose of 20 to 40 mEq/L given at a maintenance rate. Administration of potassium should not exceed a rate of 0.5 to 1 mEq/kg/hr.

Metabolic acidosis in endotoxic shock is attributable to lactic acidemia and inadequate tissue perfusion.[198] Acid-base balance often improves considerably after fluid resuscitation (preferably with alkalinizing solutions such as lactated Ringer's solution) alone; however, additional sodium bicarbonate may be required in cases in which serum bicarbonate concentration remains below 15 mEq/L. For adult horses, the bicarbonate deficit (in mEq HCO_3) is calculated as 0.3 × body mass (kg) × base deficit, whereas for foals one should use a factor of 0.5. As a general rule, one should administer half the required amount as a bolus followed by the remaining half over 12 to 24 hours. Because endotoxemia is a dynamic process and losses are ongoing, one should reevaluate acid-base status at least once daily.

Foals with sepsis are frequently hypoglycemic, and 5% dextrose solutions are useful as initial resuscitation fluids. One should reduce the glucose concentration of intravenous solutions according to the blood glucose concentration to avoid prolonged hyperglycemia. Administration of hyperimmune plasma (20 to 40 ml/kg body mass) is highly recommended in foals with evidence of partial or complete failure of passive transfer.

One should consider positive inotropic and vasomotor agents in patients with persistently inadequate tissue perfusion. Lower dosages of dopamine (0.5 to 2 μg/kg/min) result in vasodilation of the renal, mesenteric, coronary, and intracerebral vasculature via dopaminergic effects, whereas higher dosages (up to 10 μg/kg/min) also exer t stimulation of β_1-adrenergic receptors, resulting in increased myocardial contractility and heart rate.[199] Dobutamine is a direct β_1-adrenergic agonist and does not appear to have significant vasodilator properties. Dosages for dobutamine of 1 to 5 μg/kg/min as continuous intravenous infusion have been recommended for use in horses. In addition, norepinephrine was evaluated in hypotensive critically ill foals that were refractory to the effects of dopamine and dobutamine.[200] At dosages up to 1.5 μg/kg/min administered concurrently with dobutamine, six out of seven foals showed an increase in mean arterial pressure, and all foals had increased urine output. Because of the risk of cardiac side effects, close 839
monitoring of heart rate and rhythm should accompany infusion of inotropes. Indirect blood pressure 840
measurements using a tail cuff may be used to monitor the effects of treatment.

13.7.9.6.2

Management of Coagulopathy

More frequently than overt thrombosis or bleeding attributable to DIC, hemostatic abnormalities occur in the form of alterations in the coagulation profile. A procoagulant state with shortened bleeding times or prolonged bleeding times caused by consumption of clotting factors may be evident. One should address abnormalities in the coagulation profile as early as possible but especially if they persist more than 24 hours after initiation of therapy. Because of the complex interactions of coagulation and fibrinolysis during endotoxemia, one should combine anticoagulant therapy with the administration of fresh frozen plasma to replace clotting and fibrinolytic factors. Heparin acts as an anticoagulant by activation of AT III and subsequent inhibition of thrombin, release of tissue factor pathway inhibitor from endothelial cells, and inhibition of platelet aggregation.[201] Because endogenous AT III levels frequently are decreased in patients with coagulopathy, addition of heparin to fresh frozen plasma may be the most effective route of administration. An initial dose of 100 IU/kg body mass followed by 40 to 80 IU/kg body mass 3 times daily has been recommended.[121] Anemia caused by erythrocyte agglutination occurs in some patients during therapy with unfractionated heparin[202,203] but typically resolves within 96 hours if therapy is discontinued.[121] Because of the risk of microthrombosis associated with erythrocyte agglutination, use of low-molecular-weight heparin (50 IU/kg body mass subcutaneously every 24 hours) has been recommended[204] but may be cost-prohibitive. One may give aspirin orally (10 to 20 mg/kg body mass, every 48 hours), which irreversibly inhibits platelet COX activity, to inhibit platelet aggregation and microthrombosis. Platelet hyperaggregability has been implicated in the pathogenesis of carbohydrate-induced laminitis,[205] and heparin and aspirin have been recommended to prevent development of laminitis. In an in vitro study, however, aspirin did not inhibit endotoxin-induced platelet aggregation.[206]

13.7.9.6.3

Prevention of Abortion in Pregnant Mares

Luteolysis caused by increased concentrations of $PGF_{2\alpha}$ leads to pregnancy loss in endotoxemic mares before day 55 of pregnancy.[207] Daily administration of altrenogest (Regu-Mate, Hoechst-Roussel Agri-Vet, Somerville, New Jersey) at a dose of 44 mg orally consistently prevented fetal loss in mares if administered until day 70 of pregnancy.[100] Treatment with flunixin meglumine, by blockade of $PGF_{2\alpha}$ release,[101] also may contribute to the maintenance of pregnancy in endotoxemic mares. The pathogenesis of fetal loss and abortion caused by endotoxemia, surgery, or systemic disease later in gestation is not understood completely. Proposed mechanisms include direct effects on the fetus, placental function, or placental progesterone production.[208]

13.7.9.6.4

Laminitis

The pathophysiology of laminitis caused by endotoxemia is understood incompletely; however, decreased digital blood flow[209,210] and intravascular microthrombosis have been implicated. Decreased NO production by vascular endothelial cells in response to endotoxin has been suggested as a mechanism for vasoconstriction and decreased blood flow[211]; however, use of NO donors remains controversial. Maintenance of adequate peripheral perfusion and anticoagulant and antiinflammatory therapy may be helpful in preventing and treating laminitis caused by endotoxemia.

13.7.10 Summary

Although the innate immune response to endotoxin (lipopolysaccharide) is crucially important for the preservation of homeostasis and health, large amounts of endotoxin can evoke an excessive and uncontrolled inflammatory response and result in a dysfunction of hemostatic and circulatory control mechanisms, loss of vascular integrity, and finally tissue damage. Conditions commonly associated with the development of endotoxemia in horses are acute gastrointestinal diseases, especially of ischemic and severe inflammatory nature, and localized or generalized infections. Although measuring endotoxin concentrations in equine plasma is possible, this is not feasible in a clinical setting, and one typically reaches a diagnosis of endotoxemia based on clinical signs and clinicopathologic data. Successful treatment of endotoxemia requires resolution of the primary disease process in addition to neutralization of circulating endotoxin, interference with the activities of inflammatory mediators, and general supportive care. Newer treatments, such as blockade of endotoxin-interaction with cells or interruption of cell signaling pathways, are under investigation. Possible sequelae of endotoxemia include DIC, multiple organ failure, circulatory failure, and death. Frequently, the outcome of conditions associated with endotoxemia in horses depends on the severity of associated complications; for example, renal compromise, laminitis, and abortion.

13.8 13.8—Oral Diseases

Samuel L. Jones

The word *mouth* is used commonly to signify the first part of the alimentary canal or the entrance to it.[1] The mouth is bounded laterally by the cheeks, dorsally by the palate, and ventrally by the body of the mandible and by the mylohyoideus muscles. The caudal margin is the soft palate. The mouth of the horse is long and cylindric, and when the lips are closed, the contained structures almost fill the cavity. A small space remains between the root of the tongue and the epiglottis and is termed the *oropharynx*. The cavity of the mouth is subdivided into sections by the teeth. The space external to the teeth and enclosed by the lips is termed the *vesicle of the mouth,* and in the resting state the lateral margins of the vesicle, that is, the buccal mucosa, are in close contact with the cheek teeth. Caudally, the external space communicates with the pharynx through the aditus pharyngis. The mucous membrane of the mouth is continuous at the margin of the lips with the skin and during life is chiefly pink but can be more or less pigmented, depending on the skin color and the breed type.

13.8.1 Morphology and Function

The lips are two muscular membranous folds that unite at angles close to the first cheek teeth. Each lip presents an outer and an inner surface. The upper lip has a shallow median furrow (philtrum); the lower lip has a rounded prominence or chin (mentum). The internal surface is covered with a thick mucous membrane that contains

small, pitted surfaces that are the openings of the ducts of the labial glands. Small folds of the mucous membrane called the frenula labii pass from the lips to the gum. The free border of the lip is dense and bears short, stiff hairs. The arteries of the mouth are derived from the maxillary, mandibular, labial, and sphenopalatine arteries of the major palatine artery. The veins drain chiefly to the lingual facial vein. Sensory nerves originate from the trigeminal nerve (cranial nerve V) and the motor nerves from the facial nerve (VII). The cheeks spread back from the lips and form both sides of the mouth and are attached to the alveolar borders of the bones of the jaws. The cheeks are composed of skin and muscular and glandular layers and then the internal mucous membrane. The skin is thin and pliable. In contrast, the oral mucous membrane is dense and in many areas of the oral cavity is attached firmly to the periosteum so that construction of oral mucosal flaps can be achieved only by horizontal division of the periosteal attachment. Such a feature is important in reconstructive techniques applied to the oral cavity. The blood supply to the cheeks comes from the facial and buccal arteries and the sensory nerves from the trigeminal and motor nerves from the facial nerve.

The hard palate (palatum durum) is bounded rostrally and laterally by the alveolar arches and is continuous with the soft palate caudally. The hard palate has a centra l raphe that divides the surface into two equal portions. From the line of the rostral cheek tooth, the hard palate is concave to the line of the caudal cheek tooth. Paired transverse ridges (about 18) traverse the concavity and have their free edges directed caudally. The incisive duct is a small tube of mucous membrane that extends obliquely through the palatine fissure. The dorsal component
communicates by a slitlike opening in the rostral portion of the ventral nasal meatus and its palatine end is blind 846
and lies in the submucosa of the palate. When stallions display their flehmen response, watery secretions enter 847
the nose from the glands of the vomeronasal duct. To what extent these secretions aid in pheromone reception is not known.[2]

That portion of the palatine mucosa immediately behind the incisor teeth frequently is swollen (lampas) during eruption of the permanent teeth. This swelling is physiologic and not pathologic.

The tongue is situated on the floor of the mouth between the bodies of the mandible and is supported by the sling formed by the mylohyoideus muscles. The root of the tongue is attached to the hyoid bone, soft palate, and pharynx. The upper surface and the rostral portion of the tongue are free; the body of the tongue has three surfaces. The apex of the tongue is spatulate and has a rounded border. The mucous membrane adheres intimately to the adjacent structure and on the dorsum is dense and thick. From the lower surface of the free part of the tongue, a fold of mucous membrane passes to the floor of the mouth forming the lingual frenulum. Caudally, a fold passes on each side of the dorsum to join the soft palate, forming the palatoglossal arch. Dorsally from the soft palate the palatopharyngeal arch attaches and circumvents the aditus laryngis and attaches to the roof of the nasopharynx. The mucous membrane of the tongue presents four kinds of papillae:

1. *Filiform papillae* are fine threadlike projections across the dorsum of the tongue. They are absent on the root of the tongue and are small on the rostral portion of the tongue.
2. The *fungiform papillae* are larger and easily seen at the rounded free end. They occur principally on the lateral portion of the tongue.
3. *Vallate papillae* are usually two or three in number and are found on the caudal portion of the dorsum of the tongue. The free surface bears numerous small, round secondary papillae.
4. Foliate papillae are situated rostral to the palatoglossal arches of the soft palate where they form a rounded eminence about 2 or 3 cm in length marked by transverse fissures.

Foliate, vallate, and fungiform papillae are covered with taste buds and secondary papillae.

The lingual and sublingual arteries supply the tongue from the linguofacial trunk and matching veins. The linguofacial trunk drains into the linguofacial vein. The lingual muscles are innervated by the hypoglossal nerve (XII) and the sensory supply is from the lingual and glossopharyngeal (IX) nerves.

13.8.2 Equine Dentition

The formula for the deciduous teeth of the horse is 2 times I3-3 C0-0 P3-3 for a total of 24. The permanent dental formula is 2 times I3-3 C1-1 P3-3 or P4-3 M3-3 for a total of 40 or 42. In the mare the canine teeth are usually small or do not erupt, hence reducing the number to 36 or 38. The first premolar tooth (wolf tooth) is often absent and has been reported as occurring in only 20% of the upper dentition of Thoroughbred horses.[3] The teeth of the horse are complex in shape and are compounded of different materials (dentin, cementum, and enamel). They function as grinding blades to masticate and macerate cellulose food in the important first stage of the digestive process. The cheek teeth in the horse are a well-documented feature of the evolution of *Equus caballus*.

13.8.2.1 DECIDUOUS TEETH

The first incisor is present at birth or the first week of life. The second incisor erupts at 4 to 6 weeks of age; the third incisor, at 6 to 9 months of age; the first and second premolars, at birth to 2 weeks of age; and the third premolar, 3 months of age.

13.8.2.2 PERMANENT TEETH

The eruption times for the permanent teeth are as follows: first incisor, 2½ years of age; second incisor, 3½years of age; third incisor, 4½ years of age; the canine tooth, 4 to 5 years of age; the first premolar (wolf tooth), 5 to 6 months of age; the second premolar, 2½ years of age; the third premolar, 3 years of age; the fourth premolar, 4 years of age; the first molar, 10 to 12 months of age; the second molar, 2 years of age; and the third molar, 3½ to 4 years of age. This eruption sequence clearly indicates that the eruption of the second and third permanent premolar teeth give the potential for dental impaction.

The modern horse has six incisor teeth in each jaw that are placed close together so that the labile edges form a semicircle. The occlusal surface has a deep enamel invagination (infundibulum) that is filled only partially with cementum. As the incisor teeth wear, a characteristic pattern forms in which the infundibulum is surrounded by rings of enamel, dentin, enamel, and crown cementum in a concentric pattern. Each incisor tooth tapers from a broad crown to a narrow root so that as the midportion of the incisor is exposed to wear, the cross-sectional diameters are about equal; that is, at 14 years of age, the central incisor tooth of the horse has an occlusal surface that is an equilateral triangle. Observations on the state of eruption, the angles of incidence of the incisor teeth, and the pattern of the occlusal surfaces are used as guides for aging of horses. The canine teeth are simple teeth without complex crowns and are curved. The crown is compressed and is smooth on its labial aspect but carries two ridges on its lingual aspect. No occlusal contact occurs between the upper and lower canine teeth. 847

848

When erupted, the six cheek teeth of the horse function as a single unit in the mastication of food. Each arcade consists of three premolar and three molar teeth. The maxillary arcade is slightly curved, and the teeth have a square occlusal surface. The occlusal surfaces of the mandibular teeth are more oblong, and each arcade is straighter. The horse is anisognathic, that is, the distance between the mandibular teeth is narrower (one-third)

than the distance between the upper cheek teeth. This anatomic arrangement affects the inclination of the dental arcade as the jaws slide across each other in the food preparation process. The unworn upper cheek tooth presents a surface with two undulating and narrow ridges, one of which is lateral and the other medial. On the rostral and lingual side of the medial style is an extra hillock. The central portion of these surfaces is indented by two depressions that are comparable with, but much deeper than, the infundibula of the incisor teeth. When the teeth have been subjected to wear, the enamel that closed the ridges is worn through and the underlying dentin appears on the surface. Thus after a time the chewing surface displays a complicated pattern that may be likened to the outline of an ornate letter *B,* the upright stroke of the *B* being on the lingual aspect. Dentin supports the enamel internally, cementum supports the enamel lakes, and the peripheral cementum fills in the spaces between the teeth so that all six teeth may function as a single unit, that is, the dental arcade. Transverse ridges cross each tooth so that the whole maxillary arcade consists of a serrated edge. The serrations are formed so that a valley is present at the area of contact with adjacent teeth. These serrations match fitting serrations on the mandibular arcade.

The true roots of the cheek teeth are short compared with the total length of the tooth. Cheek teeth have three roots: two small lateral roots and one large medial root. By custom, that portion of the crown embedded within the dental alveolus is referred to as the *reserve crown,* and the term *root* is confined to that area of the tooth that is comparatively short and enamel free. Wear on the tooth gradually exposes the reserve crown, and the roots lengthen. In an adult 1000-lb horse the maxillary cheek teeth are between 8.0 and 8.5 cm in length. Dental wear accounts for erosion and loss of tooth substance at a rate of 2 mm/yr.

The pulp chambers of the teeth are also complex. The incisors and canines have a single pulp chamber. The mandibular cheek teeth have two roots and two separate pulp chambers. The maxillary cheek teeth, although they have three roots, have in fact five pulp chambers. As occlusal wear proceeds, deposition of secondary dentin within the pulp chambers protects the chambers (e.g., the dental star, medial to the infundibulum on the incisor teeth).

In the mandibular cheek teeth the transverse folding of the enamel anlage (during morphogenesis of the tooth) does not take place, and the occlusal surface is a simple surface of central dentin surrounded by enamel. Each tooth then is conformed to a single arcade by the presence of peripheral crown cementum.

13.8.3 Mouth Diseases

The oral cavity and oropharynx are subject to a variety of diseases. However, many conditions affecting the first portion of the alimentary system produce the same clinical signs, regardless of their cause. The clinical signs may include inappetance or reluctance to eat, pain on eating or swallowing, oral swelling, oral discharge, and fetid breath. Affected animals may show some interest in food but hesitate to eat it. Salivation may be excessive and may be contaminated with purulent exudate or blood. The occurrence of bruxism (i.e., grinding of teeth) can indicate discomfort in other areas of the alimentary tract; for example, bruxism and frothing oral saliva are characteristic features of gastric ulceration in the horse.

The clinician needs to be aware that considerable weight loss can occur rapidly with inability to feed and swallow. Diseases that result in denervation of the pharynx and inappropriate swallowing can have the complication of inhalation pneumonia.

13.8.3.1 EXAMINATION AND CLINICAL SIGNS

After a complete physical examination and ascertaining the history, the clinician should approach examination of the mouth systematically in all cases. One can examine a considerable portion of the mouth and teeth from the outside by palpation of the structures through the folds of the cheek. Most horses allow an oral examination without sedation or the use of an oral speculum. In many cases, however, one best achieves the detailed oral examination by sedation and the use of an oral speculum and a light source. One should irrigate the mouth to wash out retained food material so as to be able to inspect and palpate the lips, cheeks, teeth, and gums.

The classic signs of dental disease in the horse include difficulty and slowness in feeding, together with a progressive unthriftiness and loss of body condition. In some instances, the horse may quid, that is, it may drop poorly masticated food boluses from the mouth, and halitosis may be obvious. Additional problems reported by owners include bitting and riding problems and headshaking or head shyness. Facial or mandibular swelling may occur. Nasal discharge can result from dental disease associated with maxillary sinus empyema. Mandibular fistulae frequently are caused by lower cheek tooth apical infections. Some correlation exists between the age of the animal and clinical signs (Table 13.8-1). 848

TABLE 13.8-1 Correlation Between Dental Disease and Dental Therapy

AGE	EXAMINE FOR	NECESSARY DENTISTRY
2–3 years	1. First premolar vestige (wolf teeth)	1. Remove wolf teeth if present.
	2. First deciduous premolar (upper and lower)	2. Remove deciduous teeth if ready; if not, file off corners and points of premolars.
	3. Hard swelling on ventral surface of mandible beneath first premolar	3. Obtain x-ray film; extract retained temporary premolar if present.
	4. Cuts or abrasions on inside of cheek in region of the second premolars and molars	4. Lightly float or dress all molars and premolars if necessary.
	5. Sharp protuberances on all premolars and molars	5. Rasp protuberances down to level of other teeth in arcade.
3–4 years	1. (1), (2), (4), and (5) above	1. (1), (2), (4), and (5) above
	2. Second deciduous premolar (upper and lower)	2. Remove if present and ready.
4–5 years	1. (1), (4), and (5) above	1. (1), (4), and (5) above
	2. Third deciduous premolar	2. Remove if present and ready.
5 yrs and older	1. (1), (4), and (5) above	1. (1), (4), and (5) above
	2. Uneven growth and "wavy" arcade	2. Straighten if interfering with mastication.
	3. Unusually long molars and premolars	3. Unusually long molars and premolars may have to be cut if they cannot be filed down.

13.8.3.2

ANCILLARY DIAGNOSTIC TECHNIQUES

Ancillary aids for a complete examination of the oral cavity of the horse may include radiology, endoscopic examination, fluoroscopy, biopsy, and culture. One should take care always during endoscopic evaluation of the oral cavity using a flexible endoscope. The author recommends sedation and the use of an oral speculum to prevent inadvertent mastication of the endoscope. If one uses general anesthesia as part of the diagnostic workup, then endoscopic evaluation of the oral cavity is much easier. In selected cases, advanced imaging technologies such as computed tomography, magnetic resonance imaging, or nuclear scintigraphy may be beneficial.

13.8.4 Dysphagia

13.8.4.1 CLINICAL SIGNS AND DIAGNOSIS

The lips of the horse are mobile and prehensile. In many ways they function like the tip of the elephant's trunk in that they test, manipulate, and sample the environment for potential nutritive value. Consequently, loss of motor function (e.g., facial palsy) affects the efficiency of the prehensile system. The lips grasp food in grazing or browsing, and the incisor teeth section the food. With mastication and lubrication with saliva, the bolus of food forms and is manipulated from side to side across the mouth, assisted by the tight cheeks of the horse and the palatine ridges. Swallowing begins as the food bolus contacts the base of the tongue and the pharyngeal walls. During swallowing, the soft palate elevates to close the nasopharynx, the base of the tongue elevates, and the hyoid bone and the larynx move rostrally following contraction of the hyoid muscles. During this process, the rima glottidis closes and the epiglottis tilts dorsally and caudally to protect the airway so that food is swept through lateral food channels around the sides of the larynx into the laryngoesophagus. Fluoroscopic studies in nursing foals in the dorsoventral view showed that contact occurs between the lateral food channels in the midline so that in outline the food bolus achieves a bow tie shape.[4]

Dysphagia is defined as a difficulty or inability to swallow. Anatomic classifications for dysphagia include prepharyngeal, pharyngeal, and esophageal (postpharyngeal) dysphagias. The site of the cause for dysphagia influences the clinical signs. Prepharyngeal dysphagia is characterized by dropping food (quidding) or water from the mouth, reluctance to chew, hypersalivation, or abnormalities in prehension. Pharyngeal and esophageal dysphagias are characterized by coughing; nasal discharge containing saliva, water, or food material; gagging; anxiousness; and neck extension during attempts to swallow. The following section describes esophageal dysphagia in more detail. Causes of dysphagia can be divided into four types: painful, muscular, neurologic, or obstructive (Table 13.8-2). Pain and obstruction cause dysphagia by interfering with 849
the mechanics of prehension, bolus formation and transfer to the pharynx, and deglutition. Muscular and 850
neurologic causes of dysphagia impede prehension and swallowing by affecting the motor function of the lingual or buccal musculature, muscles of mastication (temporal and masseters), and pharyngeal and cranial esophageal muscles. Sensory loss to the lips, buccal mucous membranes, pharynx, or tongue also may cause dysphagia. Neurologic causes of dysphagia may affect the forebrain, brainstem, or peripheral nerves that control prehension (cranial nerves Vm, Vs, VII, and XII), transfer of the food bolus to the pharynx (cranial nerves Vs and XII) and swallowing (cranial nerves IX and X).

TABLE 13.8-2 Differential Diagnoses for Dysphagia

CLASS OF DYSPHAGIA	DIFFERENTIAL DIAGNOSES
Painful	Tooth root abscess or periodontal disease
	Broken teeth
	Abnormal dentition or wear
	Stomatitis, glossitis, or pharyngitis
	Nonsteroidal antiinflammatory drug toxicity
	Chemical irritation
	Thrush (candidiasis)
	Influenza
	Streptococcus equi
	Vesicular stomatitis virus
	Actinobacillus lignieresii
	Buccal, gingival, or glossal trauma (bits or chains)
	Foreign bodies
	Retropharyngeal lymphadenopathy or abscess
	Mandibular trauma
	Stylohyoid osteopathy
	Temporomandibular osteopathy
Muscular	Hyperkalemic periodic paralysis
	Nutritional myopathy (white muscle disease)
	Polysaccharide storage disease
	Glycogen branching enzyme deficiency
	Masseter myositis
	Hypocalcemia tetany or ecclampsia
	Myotonia
	Rectus capitis ventralis rupture
	White snakeroot toxicity
	Megaesophagus

Obstructive	Retropharyngeal abscess and lymphadenopathy
	Oral, pharyngeal, retropharyngeal, laryngeal, or esophageal malformations, injury, edema, or neoplasia
	Pharyngeal or epiglottic cysts
	Pharyngeal abscess or foreign body
	Dorsal displacement of the soft palate or rostral displacement of the palatopharyngeal arch
	Cleft palate
	Guttural pouch tympany or empyema
	Follicular pharyngitis
	Esophageal obstruction
	Pharyngeal cicatrix
	Retropharyngeal abscess or neoplasia
Neurologic forebrain disease; generalized neuropathy; disorders of cranial nerves V, VII, IX, X, or XII	Guttural pouch empyema, mycosis, or neoplasia
	Stylohyoid osteopathy
	Lead poisoning
	Petrous temporal bone osteomyelitis or fracture
	Retropharyngeal abscess
	Botulism
	Yellow star thistle toxicity
	Viral encephalitis
	Cerebral edema
	Cerebral or brainstem hemorrhage
	Intracranial masses (hematoma, neoplasia, abscess)
	Meningitis
	Verminous encephalitis
	Equine protozoal myeloencephalitis
	Equine herpesvirus 1
	Equine dysautonomia
	Hepatoencephalopathy
	Tetanus
	Polyneuritis equi

Diagnosis of the cause of dysphagia is based on physical examination including a careful oral examination, neurologic examination, clinical signs, and endoscopy of the pharynx, esophagus, and guttural pouches. Radiology may be useful to assess the bony structures of the head and throat. Ultrasonography is valuable for

examining the retropharyngeal space and esophagus to detect and evaluate masses. One may detect pharyngeal or esophageal causes of dysphagia with routine endoscopic examination or with contrast radiography. Although one also can use endoscopy to assess deglutition, one must remember that sedation adversely affects the deglutition mechanism. One may assess deglutition using fluoroscopy[4] or manometry,[5] but these techniques require specialized equipment. Specific diagnostic procedures for nonalimentary causes of dysphagia are covered elsewhere in this text (see Chapter 3).

13.8.4.2

MANAGEMENT

Specific treatments aimed at resolving the underlying disorder causing dysphagia are discussed in detail elsewhere. One should avoid feeding roughage with long fiber length (hay or grass) to most horses with dysphagia. Dietary modifications that promote swallowing such as feeding slurries made from complete pelleted feeds may be sufficient to manage some cases of partial dysphagia. One must take care to prevent or 850
avoid aspiration pneumonia in horses with pharyngeal or esophageal dysphagia. One can manage foals by 851
feeding mare's milk or a suitable substitute through a nasogastric tube. One also may administer pellet slurries or formulated liquid diets via nasogastric tubes to older horses. Prolonged nutritional management of dysphagic horses may require extraoral feeding using a tube placed through an esophagostomy.[6]

Formulated pelleted diets are often easy to administer through a tube as slurry and are balanced to meet the nutritional requirements for healthy horses. One must feed sufficient quantities to deliver adequate calories (16 to 17 Mcal/day for a 500-kg horse). Adjustments may be necessary for horses that are cachectic or have extra metabolic demand (such as pregnancy). Adding corn oil to the ration (1 cup every 12 or 24 hours) is a common method of increasing fed calories. Liquid diets also have been used for enteral feeding[7] but may not be tolerated as well as pelleted diets. Regardless of the method of nutritional management, one must monitor and replace salivary losses of electrolytes. Saliva contains high concentrations of Na, K, and Cl. A group of ponies with experimental esophagostomies[8] and a horse with esophageal squamous cell carcinoma[9] were fed a complete pelleted diet through esophagostomy tubes but developed metabolic acidosis, hyponatremia, and hypochloremia apparently because of salivary losses. Surprisingly, salivary losses of potassium did not result in hypokalemia in these cases, presumably because of replacement in the diet. However, if the diet is deficient in potassium, hypokalemia may result. One often can accomplish electrolyte replacement by adding NaCl and KCl to the diet. One can maintain horses for months with frequent feedings through an esophagostomy tube.[9] Parenteral nutrition (total or partial) may be useful in the short term but is not often feasible for long-term management.

TABLE 13.8-3 Sites of Apical Infections in Diseased Cheek Teeth

13.8.5

Dental Diseases

13.8.5.1

ERUPTION DISORDERS

Tooth eruption is a complex phenomenon involving the interplay of dental morphogenesis and those vascular forces responsible for creating the eruption pathway. These changes are responsible for osteitis and bone remodeling within the maxilla and mandible. Young horses frequently show symmetric bony swelling resulting from these eruption cysts. In some cases, additional clinical signs of nasal obstruction with respiratory stridor or nasal discharges may be apparent.

Pathologic problems associated with maleruption include a variety of dental diseases. Oral trauma can displace or damage erupting teeth or the permanent tooth buds. As a result, teeth may be displaced and erupt in abnormal positions or may have abnormal shapes. Supernumerary teeth, incisors and molars, can develop, as well as palatal displacement of impacted teeth (maxillary P3-3, or third cheek tooth). In almost all of these conditions some form of surgical treatment is necessary.

Significant evidence from the location of apical osteitis in diseased teeth (Table 13.8-3) confirms that dental impaction is a major cause of dental disease in the horse. In a series of 142 extracted teeth, 63 were P3-3 or P4-4 (cheek tooth 2 or 3, respectively).[10] Early observations had indicated that the first molar (M1, or cheek tooth 4) was the most commonly diseased tooth, and an "open infundibulum" in this tooth has been suggested as the cause.[11] Studies on cementogenesis of the maxillary cheek teeth have shown, however, that in fact most maxillary cheek teeth have a greater or lesser degree of hypoplasia of cementum within the enamel lakes and that this "lesion" rarely expands into the pulp. The central infundibular hole is the site of its vascular supply to 851
the unerupted cement lake. On those occasions in which caries of cementum occurs, that is, secondary 852
inflammatory disease and acid necrosis of the cementum, apical osteitis may develop.

13.8.5.2

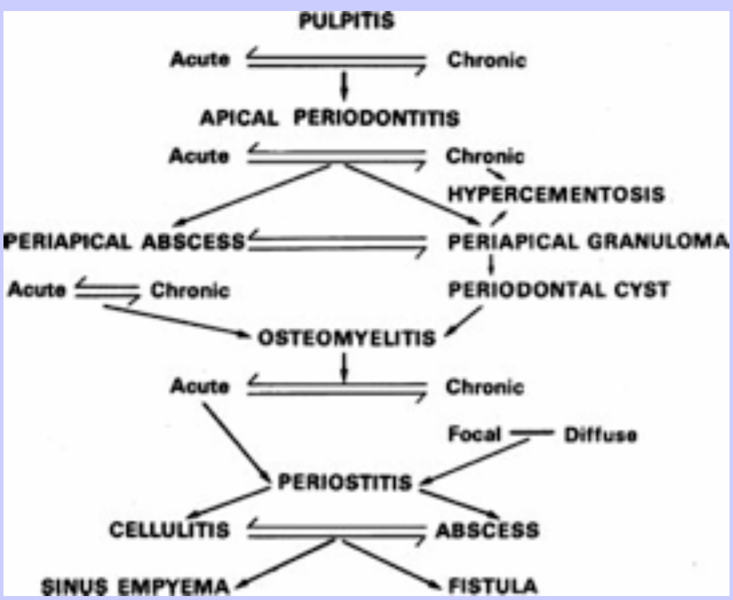
DENTAL DECAY

Pulpitis is key to the pathogenesis of dental decay in the horse. The initiation of inflammatory pulp changes may be a sequela to dental impaction or dental caries or may result from fracture of a tooth. If the onset of the inflammatory process is slow, then formation of secondary dentin within the pulp chambers may protect the pulp and the tooth. Secondary dentin formation occurs from stimulation of odontoblasts within the pulp chamber. Such changes are the normal process of protection during dental wear and attrition as crown substances wear away and the reserve crown comes into wear. In acute disease, however, this defense mechanism is ineffective, and the changes that occur and that are sequelae to pulpitis reflect the location of each affected tooth. For example, pulpitis and apical osteitis of the third mandibular cheek tooth most commonly results in the development of a mandibular dental fistula. Pulpitis of the third maxillary cheek tooth, however, results in an inflammatory disease within the rostral maxillary sinus and in development of chronic maxillary sinus empyema (Figure 13.8-1).

Oblique radiographs greatly assist the diagnosis of dental decay by demonstrating sinus tract formation, sequestration of bone, mandibular osteitis, hyperplasia of cementum, and new bone formation (so-called alveolar periosteitis).[12]

The management of dental decay in the horse usually involves surgical extraction of the diseased tooth. In some cases one can use apicoectomy and retrograde endodontic techniques to save the diseased tooth. One must take care, however, in selection of patients. In most cases of apical osteitis in the horse that result from dental impaction, immature root structures make achieving an apical seal of the exposed pulp difficult.

Figure 13.8-1 Possible sequelae to pulpitis in the horse. (From Baker GJ: Disease of the teeth. In Colohan PT, Mayhew IG, Merritt AM et al, editors: *Equine medicine and surgery*, ed 4, vol 1, Goleta, Calif, 1991, American Veterinary Publications.)



13.8.6 Periodontal Disease

Gingival hyperemia and inflammation occur during the eruption of the permanent teeth and are common causes of a sore mouth in young horses (particularly 3-year-olds as the first dental caps loosen). Such periodontal changes usually resolve as the permanent dental arcade is established. During normal mastication, the shearing forces generated by the occlusal contact of the cheek teeth essentially clean the teeth of plaque and effectively inhibit deposition of dental calculus. Wherever occlusal contact is ineffective, periodontal changes and calculus buildup occur; for example, the deposition of calculus on the canine teeth of mature geldings and stallions is common. Routine dental prophylaxis forms an important component of maintaining normal occlusal contact, and for this reason one should remove arcade irregularities that result in enamel point formation on the buccal edges of the maxillary cheek teeth and the lingual edges of the mandibular cheek teeth. One should remove these edges annually in horses that are at grass and twice yearly in young horses, aged horses, and stabled horses. Horses at grass have been shown to have a greater range of occlusal contact and therefore better periodontal hygiene than stabled horses. In stabled horses the range of occlusal contact is narrower and the formation of enamel points occurs more frequently with subsequent buccal ulceration and the initiation of a cycle of altered occlusal contact and hence irregular arcade formation. This process leads to severe forms of periodontal disease and wave mouth formation.

Periodontal disease occurs with abnormal occlusal contact and initiation of the cycle of irregular wear and abnormal contact. Such changes progress to loss of alveolar bone, gross periodontal sepsis, and loss of tooth support. In this sense periodontal disease truly is the scourge of the equine mouth and results in tooth loss.[13]

13.8.7 Congenital and Developmental Abnormalities

13.8.7.1 CLEFT PALATE

Palatine clefts may result from an inherited defect and are caused by failure of the transverse palatal folds to
fuse in the oral cavity. Harelip accompanies few palatine clefts in the horse. The degree of palatine clefting 852
depends on the stage at which interruption in the fusion of the palatopalatal folds occurs. Toxic or teratogenic 853
effects are documented in other species, but little data are available in the horse.

In recent years, treatment for repair of uncomplicated palatine defects has been recommended but prognosis is generally poor because of the considerable nursing care required and the high incidence of surgical failures. One should emphasize early surgery and the use of mandibular symphysiotomy in affording surgical exposure. The combination of mandibular symphysiotomy and transhyoid pharyngotomy to approach the caudal margins of the soft palate affords surgical access, and one can construct mucosal flaps to repair the defects. However, the incidence of surgical breakdown is high, and healing by first intention is the exception rather than the rule. A recent surgical report documented the successful closure of a median cleft of the lower lip and mandible in a donkey.[14]

13.8.7.2 CAMPYLORHINUS LATERALIS

Foals born with a severely deviated premaxilla and palate have a wry nose. One can achieve surgical correction of the deviated premaxilla by submucosal division of the premaxilla across the nose at the line of

the first cheek tooth. Circumstantial evidence indicates that such a defect has a genetic cause, and the defect occurs most frequently in the Arabian breed.

13.8.7.3 CYSTS

Other developmental abnormalities are subepiglottic cysts resulting from cystic distortion of remnants of the thyroglossal duct, which may cause dyspnea and choking in foals. Surgical removal of these cysts results in normal function.

13.8.7.4 PARROT MOUTH

The most significant developmental defect of dental origin is a maxilla that is longer than the mandible, that is, the horse is parrot-mouthed. An overbite of 2 cm in the incisor arcade may be present in a horse with a mismatch of less than 1 cm between the first upper and lower cheek teeth. Parrot mouth and monkey or sow mouth are thought to be inherited conditions. Some correction of minor incisor malocclusion occurs up to 5 years of age.

Recognition and detection of parrot mouth are important in the examination of potential breeding stock. Surgical attempts to inhibit overgrowth of the premaxilla by wiring or by the application of dental bite plate procedures have been documented in recent years.[15]

13.8.8 Oral Wounds

As has been indicated, the horse is by nature a curious animal and uses its lips as a means of exploring a variety of objects. Wounds of the lips, incisive bone, and the mandibular incisor area occur commonly in the horse and usually result from the horse getting the lips, jaw, or teeth caught in feeding buckets, in fence posts, or in halters or having a segment of tongue encircled with hair in tail chewing. As the horse panics and pulls away from its oral entrapment, considerable trauma can occur to the lips, teeth, and gums.

Most wounds repair satisfactorily, provided one finds them early and observes the basic principles of wound hygiene, excision of necrotic tissue, and wound closure. One must ensure that oral mucosal defects are closed and that effective oral seals are made before external wounds are closed. In some cases, offering specially constructed diets or even feeding the horse by nasogastric tube or esophagostomy during the healing processes may be necessary.

13.8.9 Stomatitis and Glossitis

Foreign body penetration of the tongue, cheek, or palate has been reported in grazing and browsing horses and in particular in horses that have certain hay sources that contain desiccated barley awns or yellow bristle grass.[16] Other plant material and grass awns also occasionally may penetrate the tongue, gingiva, or cheek, causing inflammation or abscesses. Ulcerative stomatitis also results from the toxicity of phenylbutazone therapy.[17] Vesicular stomatitis is a highly contagious viral blistering disease described in more detail elsewhere. Treatment of glossitis and stomatitis primarily aims at removing the inciting cause.

Actinobacillus lignieresii, the causative agent of actinobacillosis, has been isolated and identified from ulcers on the free border of the soft palate and oral and laryngeal granulomata. The bacterium also was reported in a

sublingual caruncle in a horse with a greatly swollen tongue.[18] Therapy with 150 ml of 20% sodium iodide and 5 g of ampicillin every 8 to 12 hours effected a clinical cure.

13.8.10 Salivary Glands

13.8.10.1 FUNCTION

Saliva is important for lubricating and softening food material. The horse has paired parotid, mandibular, and polystomatic sublingual salivary glands. The parotid gland is the largest of the salivary glands in the horse and is situated in the space between the ramus of the mandible and the wing of the atlas. The parotid duct is formed at the ventral part of the gland near the facial crest by the union of three or four smaller ducts. The duct leaves the gland above the linguofacial vein, crosses the tendon of the sternocephalicus muscle, and enters the 853
mouth obliquely in the cheek opposite the third upper cheek tooth. The parotic duct orifice is small, but some 854
dilation of the duct and a circular mucous fold (the parotid papillae) exist at this point. The mandibular gland is smaller than the parotid gland and extends from the atlantal fossa to the basihyoid bone. For the most part, the mandibular gland is covered by the parotid gland and by the lower jaw. The mandibular duct is formed by union of a number of small duct radicles that emerge along the concave edge of the gland and run rostral to the border of the mouth opposite the canine tooth. The orifice is at the end of a sublingual caruncle. The mandibular gland possesses serous, mucous, and mixed alveolar glandular components. The parotid gland is a compound alveolar serous gland. The parotid salivary gland can secrete saliva to yield rates of 50 ml/min, and a total daily parotid secretion can be as much as 12 L in a 500-kg horse. Parotid secretion only occurs during mastication, and administration of atropine or anesthesia of the oral mucosa can block secretion. Parotid saliva is hypotonic compared with plasma, but at high rates of flow, concentrations of sodium, chloride, and bicarbonate ions increase.

13.8.10.2 SALIVARY GLAND DISORDERS

Parotid saliva of the horse has a high concentration of calcium, and occasionally calculi (sialoliths) form within the duct radicles of the parotid salivary gland.[19] Congenital parotid duct atresia, acquired stricture from trauma to the duct, or obstruction by plant material (sticks or foxtails and other seeds) also may occur. The clinical signs of sialolithiasis or other forms of ductule obstruction include a fluid swelling in the form of a mucocele proximal to the stone and occasionally inflammation of the parotid gland. Ultrasonography is useful to diagnose salivary mucoceles and to detect foreign bodies or sialoliths. Measurement of electrolyte concentrations in aspirates from suspected mucoceles might be helpful to distinguish them from hematomas. Salivary potassium and calcium concentrations are higher than plasma. Treatment may require surgical removal of the stone or plant material in the case of sialolithiasis or foreign body obstructions. Other causes of obstruction may require resection of the affected portion of the duct or chemical ablation of the gland.[20]

Primary sialoadenitis is unusual but can occur in one or both glands. The condition is painful and may be associated with a fever and anorexia. Secondary sialoadenitis is more common and usually is associated with trauma. Infectious sialoadenitis from *Corynebacterium pseudotuberculosis*[21] or other bacterial pathogens also may occur. Diagnosis is by physical examination and by finding an enlarged edematous parotid gland tissue on ultrasonographic examination. Culture and cytologic examination of aspirates may be useful for diagnostic purposes. Treatment in usually palliative, consisting of nonsteroidal antiinflammatory drugs. Appropriate antibiotic therapy is indicated as directed by culture and sensitivity results.

Chemical irritation, glossitis, stomatitis, or other causes of prepharyngeal dysphagia cause ptyalism or excessive salivation in horses. Specific therapy for the ptyalism usually is not required as long as salivary losses are not excessive, resulting in dehydration and electrolyte imbalances. Ingestion of the fungal toxin slaframine also causes hypersalivation in horses.[22] The fungus *Rhizoctonia leguminicola*, which produces slaframine, causes black patch disease in red clover. Slaframine is a parasympathomimetic compound that stimulates exocrine secretion in the parotid gland. Slaframine toxicosis most commonly occurs in the spring or early summer and rarely requires treatment other than removal from the pasture. Mowing removes the source in most cases because regrowth in pastures often has less fungal contamination.[23]

13.9—Esophageal Diseases

Samuel L. Jones

Anthony T. Blikslager

13.9.1

Anatomy and Function

The esophagus is a musculomembranous tube that originates from the pharynx dorsal to the larynx and terminates at the cardia of the stomach.[1] In adult Thoroughbred horses the esophagus is approximately 120 cm long. The cervical portion is approximately 70 cm long; the thoracic portion, approximately 50 cm long; and the short abdominal portion, only approximately 2 cm long. The cervical esophagus generally lies dorsal and to the left of the trachea in the cervical region. In the thorax the esophagus courses through the mediastinum lying dorsal to the trachea and crosses to the right of the aortic arch dorsal to the heart base.

The esophagus has no digestive or absorptive functions and serves as a conduit to the stomach for food, water, and salivary secretions. The esophageal mucosa is a keratinized stratified squamous epithelium.[1] The submucosa contains elastic fibers that contribute to the longitudinal folds of the esophagus and confer elasticity to the esophageal wall. A transition occurs in the muscle type composing the tunica muscularis from striated skeletal muscle in the proximal two thirds of the esophagus to smooth muscle in the distal third. In the proximal esophagus the skeletal muscle layers spiral across one another at angles. Within the smooth muscle layers of the distal esophagus the outer layer becomes more longitudinal, whereas the inner layer thickens and becomes circular. The wall of the terminal esophagus can be 1 to 2 cm thick. Deep cervical fascia, pleura, and peritoneum contribute to the thin fibrous tunica adventitia of the esophagus.

Motor innervation to the striated skeletal muscle of the esophagus includes the pharyngeal and esophageal branches of the vagus nerve, which originate in the nucleus ambiguus of the medulla oblongata. Parasympathetic fibers of the vagus nerve supply the smooth muscle of the distal esophagus. Sympathetic innervation of the esophagus is minimal.

Passage of ingesta through the esophagus can be considered part of the swallowing process, which consists of oral, pharyngeal, and esophageal stages. The oral stage is voluntary and involves transport of the food bolus from the mouth into the oropharynx. During the involuntary pharyngeal stage the food bolus is forced through the momentarily relaxed upper esophageal sphincter by simultaneous contractions of the pharyngeal muscles. In the esophageal phase of swallowing the upper esophageal sphincter closes immediately, the lower esophageal sphincter opens, and esophageal peristalsis propels the bolus into the stomach.[2] Unlike a food bolus, liquids do not require peristalsis to reach the lower esophageal sphincter and may precede the food bolus during swallowing.

The upper esophageal sphincter prevents esophagopharyngeal reflux during swallowing and air distention of the esophagus during inspiration. Upper esophageal pressure increases in response to pressure from a food bolus and to increased intraluminal acidity, as would occur with gastroesophageal reflux. The lower esophageal sphincter is a smooth muscle located at the gastroesophageal junction that is morphologically ill defined but forms an effective functional barrier.[2] Normally the lower esophageal sphincter is closed in response to gastric distention to restrict gastroesophageal reflux. Relaxation of the lower esophageal sphincter permits passage of ingested material from the esophagus to the stomach. Distention of the stomach with ingesta mechanically constricts the 855
lower esophageal sphincter. Gastric distention also triggers a vagal reflex that increases lower esophageal 856
sphincter tone, a safety mechanism against gastroesophageal reflux. The mechanical and vagal mechanisms that promote lower esophageal sphincter tone prevent spontaneous decompression of the stomach, which along with a lack of a vomiting reflex in the horse, increases the risk of gastric rupture during episodes of severe distention.

13.9.2 Esophageal Obstruction

Esophageal obstruction has many causes (Table 13.9-1) and most often is manifested clinically by impaction of food material and resulting esophageal dysphagia. Esophageal obstruction may be caused by primary impactions (simple choke) of roughage, particularly leafy alfalfa hay, coarse grass hay, bedding, and even grass. Prior esophageal trauma or poor mastication caused by dental abnormalities may predispose horses to primary esophageal impaction.[3] Wolfing or gulping food may precipitate primary impactions, particularly if the horse is exhausted or mildly dehydrated after a long ride or is weakened from chronic debilitation. Impactions also may result from disorders that physically impede the passage of food material and fluid by narrowing the luminal diameter, reduce the compliance of the esophageal wall, or alter the conformation of the esophageal wall such that food material accumulates in a pocket or diverticulum. Foreign bodies, intra- or extramural masses, or acquired or congenital anomalies cause these so-called secondary impactions. Intramural causes of esophageal obstruction include tumors (squamous cell carcinoma), strictures, diverticula, and cysts.[3–10] Mediastinal or cervical masses (tumors or abscesses) may cause extramural obstructions. Congenital anomalies are covered in detail later.

TABLE 13.9-1 Causes of Complete or Partial Esophageal Obstruction in the Horse

CATEGORY	DIFFERENTIAL
Intraluminal	Foreign body
	Feed material (simple impaction)
Extramural	Neoplasm (squamous cell carcinoma, lymphoma)
	Vascular ring anomaly (persistent right aortic arch)
	Granuloma
Intramural	Esophageal abscess
	Granuloma
	Neoplasm (squamous cell carcinoma, leiomyosarcoma)
	Cysts (intramural cysts, duplication cysts)
	Diverticulum
	Stenosis
Functional disorders	Dehydration
	Exhaustion
	Pharmacologic (acepromazine, detomidine)
	Primary megaesophagus (congenital ectasia)
	Esophagitis
	Autonomic dysautonomia
	Vagal neuropathies

13.9.2.1

CLINICAL SIGNS AND DIAGNOSIS

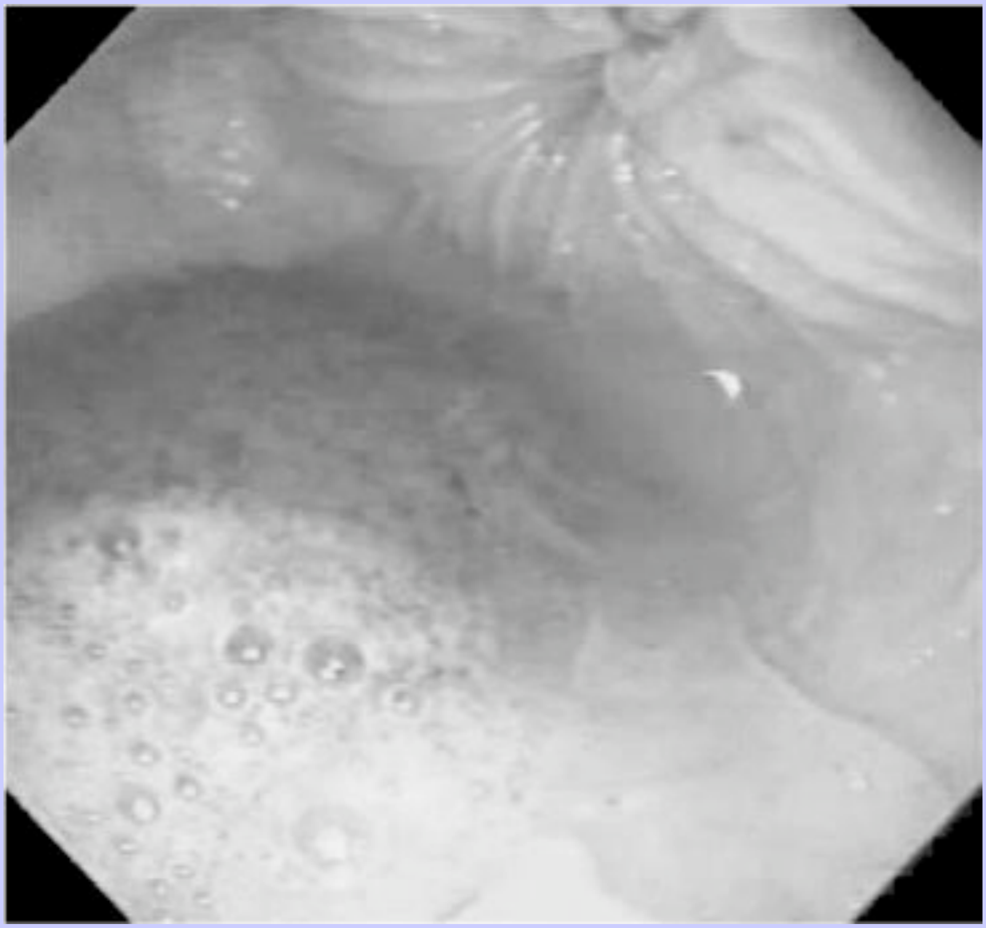
The clinician must perform a thorough physical examination, including complete oral and neurologic examination, to help rule out causes of dysphagia and nasal discharge other than esophageal obstruction. The clinical signs associated with esophageal obstructions are related primarily to regurgitation of food, water, and saliva caused by esophageal (postpharyngeal) dysphagia.[11] Horses with esophageal obstruction are often anxious and stand with their neck extended. One may note gagging or retching, particularly with acute proximal obstructions. Bilateral frothy nasal discharge containing saliva, water, and food material; coughing; odynophagia; and ptyalism are characteristic clinical signs, the severity of which varies with the degree and location of the obstruction. Distention in the jugular furrow may be evident at the site of obstruction. One may observe other clinical signs related to regurgitation of saliva, water, and food material, such as dehydration, electrolyte or acid-base imbalances, weight loss, and aspiration pneumonia. In extreme cases, pressure necrosis from the impaction or trauma to the esophagus may cause esophageal rupture. If the rupture is in the cervical esophagus, crepitus or cellulitis may be evident along with signs of systemic inflammation. Thoracic

auscultation is important to determine whether aspiration pneumonia is present. Intrathoracic esophageal rupture may result in pleuritis and its associated clinical signs.

Passage of a nasogastric tube is an effective way to detect and localize an obstruction but provides little information about the nature of the obstruction or the condition of the esophagus. The most direct method for diagnosis of esophageal obstructions is endoscopic examination. Most cases of esophageal obstruction occur at sites of natural narrowing of the esophageal lumen, such as the cervical esophagus, the thoracic inlet, base of the heart, or the terminal esophagus, thus one may need an endoscope longer than 1 m for complete evaluation. Endoscopic evaluation is useful before relief of an impaction to localize the obstruction and to investigate the nature of the impaction if one suspects a foreign body. Foreign bodies may be retrievable via transendoscopic tethering.[12] One can obtain critical diagnostic and prognostic information following resolution of the impaction. Assessing the affected esophagus for mucosal ulceration, rupture, masses, strictures, diverticula, and signs of functional abnormalities is important (Figure 13.9-1).

Ultrasonography of the cervical region is useful not only to confirm a cervical esophageal impaction but also 856
to provide critical information about the location and extent of the impaction and esophageal wall thickness 857
and integrity. Ultrasonography may provide information about the cause.[13] Radiographic assessment of the esophagus can confirm the presence of esophageal obstruction in cases in which one cannot view the affected area adequately using endoscopy. One can detect impacted food material in the esophagus by a typical granular pattern and often can observe gas accumulation proximal to the obstruction. Air or barium contrast radiographic studies are most useful for evaluating the esophagus following relief of the impaction if one suspects a stricture. One often can detect esophageal dilation, diverticula, rupture, functional disorder (megaesophagus), or luminal narrowing caused by extraluminal compression more easily using contrast radiographic studies instead of endoscopy (Figure 13.9-2).[14–16] One should take care when interpreting radiographic studies in sedated horses, particularly after passage of a nasogastric tube or other esophageal manipulations that may contribute to esophageal dilation.[17]

Figure 13.9-1 Endoscopic view of the cervical esophagus in an adult horse 6 months after an episode of choke that caused circumferential ulceration of the esophageal mucosa. The area of luminal narrowing (stricture) is at the upper right of the image, and the proximal dilation forms an outpouching of the esophageal wall. A contrast esophagram revealed that the outpouching was a pulsion diverticulum.

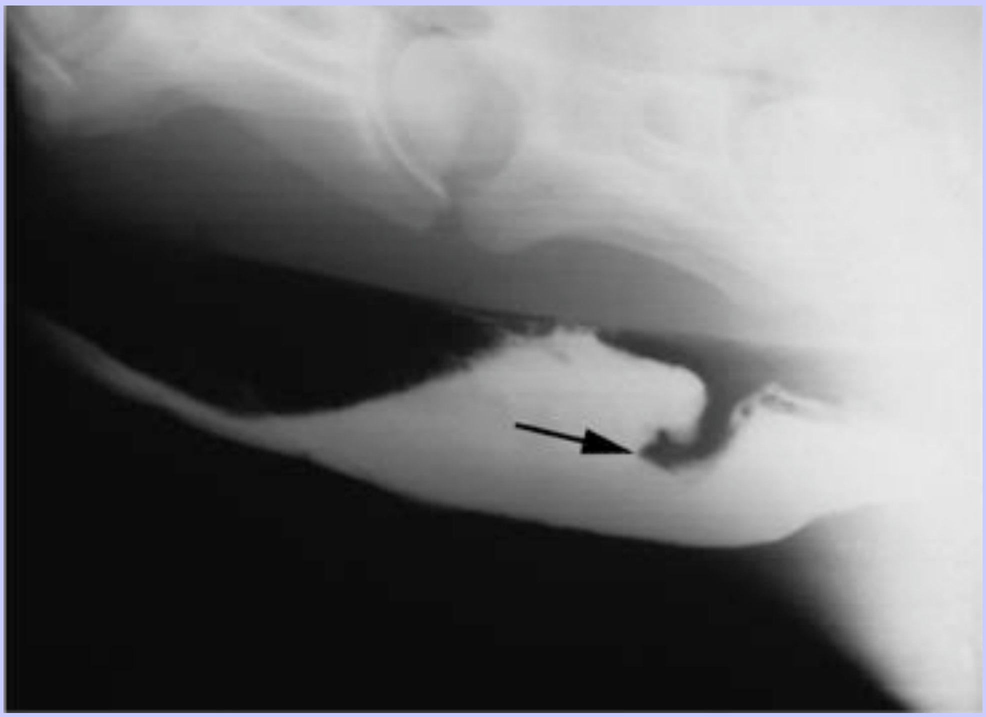


13.9.2.2 TREATMENT

The primary goal of treatment for esophageal impaction is to relieve the obstruction. Parenteral administration of acepromazine (0.05 mg/kg intravenously), xylazine (0.25 to 0.5 mg/kg intravenously) or detomidine (0.01 to 0.02 mg/kg intravenously), oxytocin (0.11 to 0.22 IU/kg intramuscularly), and/or esophageal instillation of lidocaine (30 to 60 ml of 1% lidocaine) may reduce esophageal spasms caused by pain or may decrease esophageal tone.[17–20] Some clinicians advocate parasympatholytic drugs such as atropine (0.02 mg/kg

intravenously) to reduce salivary secretions and lessen the risk of aspiration. However, undesirable effects of atropine including excessive drying of the impaction and inhibition of distal gastrointestinal motility may preclude its use.

Figure 13.9-2 Contrast esophagram in a horse with circumferential esophageal stricture *(arrow)* and a pulsion diverticulum proximal to the stricture.



Resolution of an impaction may require physical dispersal of the material.[18] One can use a nasogastric tube to displace the impacted material along with external massage if the obstruction is in the cervical region. Often, carefully lavaging the esophagus with water via an uncuffed or a cuffed nasogastric tube while the head is lowered is necessary to aid in breaking up the impaction. Some clinicians advocate a dual tube method whereby a tube is placed through each nasal passage into the esophagus for ingress and egress of the lavage fluid. Because of the risk of aspiration of water and food material, esophageal lavage sometimes is done under general anesthesia with a cuffed nasotracheal tube.

In refractory cases, intravenous administration of isotonic fluid containing 0.9% NaCl and KCl (10 to 20 mEq/L) for 24 hours at a rate of 50 to 100 ml/kg/day along with esophageal relaxants such as oxytocin may promote hydration and softening of the impaction and help prevent or alleviate any electrolyte or acid-base imbalances resulting from salivary losses of chloride, sodium, and potassium.[21] One should note that the effects of oxytocin on esophageal tone occur in the proximal two thirds of the esophagus and may not be 857
effective for distal obstructions.[19,20] Rarely, esophageal obstruction ultimately may require esophagotomy to 858
relieve the impaction. One must enforce strict restriction of food and water, including access to bedding material, until the obstruction is resolved and the esophagus has regained function.

Systemic effects of dysphagia associated with esophageal impaction include dehydration, hyponatremia, hypochloremia, and metabolic alkalosis from prolonged loss of salivary free water and electrolytes.[21] If the duration of a complete esophageal obstruction is 48 hours or longer, one should correct dehydration and electrolyte and acid-base imbalances. One can restore fluid and electrolyte balance with oral electrolyte solutions if the patient is less than 6% to 7% dehydrated and the esophageal obstruction is resolved. Horses that are greater than 6% to 7% dehydrated or those that have a refractory obstruction or moderate to severe electrolyte imbalances may require intravenous fluid therapy with solutions containing 0.9% NaCl and KCl (10 to 20 mEq/L).

One should perform esophageal endoscopy after relief of the impaction to determine whether any complications of the impaction have developed or if a primary cause of the obstruction is present. Endoscopic examination is critical to determine the postobstruction treatment plan and for follow-up evaluation of esophageal healing. One should reevaluate the horse every 2 to 4 weeks following resolution of the impaction if one notes esophageal dilation or mucosal injury. Additional evaluation via radiography may be warranted to assess motility and transit times.

Dilation proximal to the site of obstruction, mucosal injury from trauma, stricture formation, formation of a diverticulum, megaesophagus, and esophagitis are sequelae to esophageal obstruction that predispose patients to reobstruction. The rate of reobstruction may be as high as 37%. Depending on the duration of the obstruction and the degree of trauma or dilation, the risk of reobstruction is high for 24 to 48 hours or longer, thus one should withhold food for at least 24 to 48 hours after resolution of the obstruction. Sucralfate (20 mg/kg orally every 6 hours) may hasten healing if esophageal ulceration is evident, but the efficacy of sucralfate for this purpose is not established. Some clinicians suggest that administration of a nonsteroidal antiinflammatory drug (NSAID) such as flunixin meglumine (1 mg/kg orally or intravenously every 12 hours) or phenylbutazone (1 to 2 mg/kg orally or intravenously every 12 to 24 hours) for 2 to 4 weeks after resolution of the impaction may reduce the development of strictures. Judicious use of NSAIDs is recommended to prevent NSAID-induced worsening of esophageal mucosal injury. One should avoid orally administered NSAIDs if esophagitis is present. After 48 to 72 hours or when the esophageal mucosa has recovered as assessed by endoscopy, one can feed the horse soft food (moistened pellets and bran mashes). One can return the patient gradually to a high-quality roughage diet over 7 to 21 days, depending on the degree of esophageal damage induced by the impaction and the nature of any underlying disease. The prognosis for survival is good (78%), but some horses may require permanent dietary modification if persistent chronic obstruction is a problem.[3]

Aspiration pneumonia and perforation are potential complications of severe or prolonged esophageal obstructions. If aspiration is suspected, administration of broad-spectrum antibiotics that are effective against gram-positive and gram-negative organisms, including metronidazole (20 mg/kg orally every 8 hours) for anaerobes is advisable. A subsequent section describes treatment of esophageal perforation or rupture.

13.9.3 Esophagitis

Esophagitis refers to a clinical syndrome of esophageal inflammation that may or may not be ulcerative. The major protective mechanisms of the esophageal mucosa include salivary and food material buffers, normal peristaltic motility, and the barrier formed by the gastroesophageal sphincter. Reflux esophagitis is caused by repeated episodes of gastric fluid regurgitation into the distal esophagus and subsequent chemical injury to the mucosa (Figure 13.9-3).[22] Esophageal mucosal ulceration also can occur if the clearance of gastric fluid from the 858
esophagus is delayed, such as in functional disorders of the esophagus. Like ulceration of the squamous portion 859

of the stomach in horses, gastric acid and bile salt chemical injury is a major mechanism of esophageal squamous epithelial ulceration.[22,23] Reflux esophagitis may occur along with gastric ulcer disease, motility disorders, increased gastric volume from gastric outflow obstructions, gastric paresis, intestinal ileus, or impaired lower esophageal sphincter function.[7,22] Other causes of esophagitis in horses include trauma (foreign bodies, food impactions, nasogastric tubes), infection (mural abscesses), or chemical injury (pharmaceuticals, cantharidin) (Figure 13.9-4).[24–27]

Figure 13.9-3 Endoscopic view of the distal esophagus in a 7-month-old foal with duodenal obstruction. The ulcerative lesions in the distal esophagus and the generalized hyperkeratosis of the esophageal mucosa are notable.

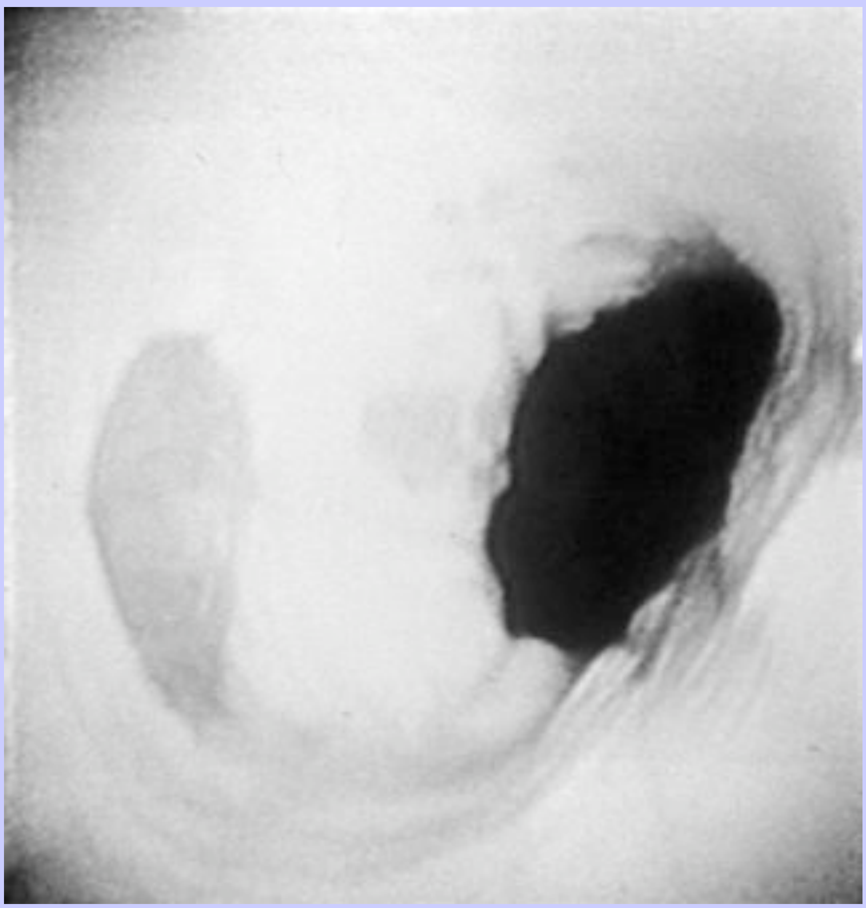


Figure 13.9-4 Endoscopic view of the cervical esophagus of a horse that had repeated passages of a stiff nasogastric tube. The deep, linear ulceration of the esophageal mucosa is notable.

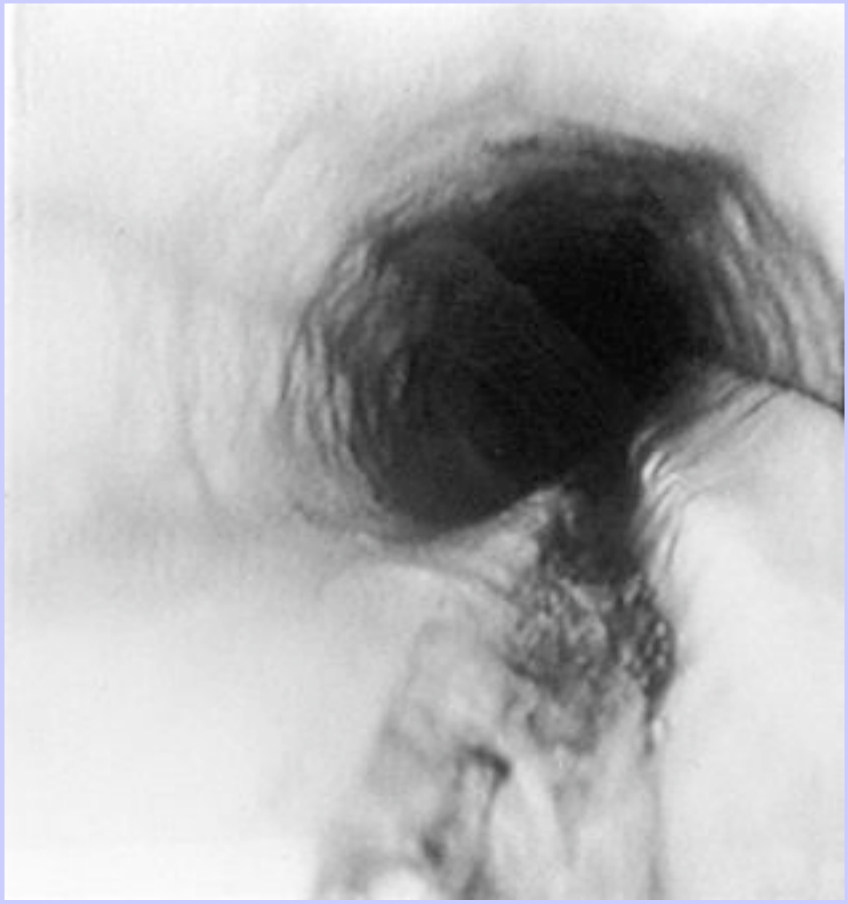

13.9.3.1

CLINICAL SIGNS AND DIAGNOSIS

The clinical signs of esophagitis are nonspecific and similar to esophageal obstruction and gastric ulcer diseases. Gagging or discomfort when swallowing may be evident, and hypersalivation and bruxism are signs of esophageal pain. Esophageal (postpharyngeal) dysphagia may be evident. One may note partial or complete anorexia such that horses with chronic esophagitis may have significant weight loss. Esophageal hypomotility dysfunction caused by the inflammatory process may result in esophageal impaction. Clinical signs of underlying diseases that predispose to esophagitis may predominate or mask the signs of esophagitis. Horses with gastrointestinal motility disorders such as proximal enteritis or gastric outflow obstruction are at a high risk of developing reflux esophagitis because of the presence of gastric acid and bile salts in the fluid reflux. Foals with gastric, pyloric, or duodenal strictures caused by chronic ulceration commonly have reflux esophagitis.

Diagnosis requires endoscopic examination of the esophagus. One may note diffuse, patchy, linear, or coalescing erosion or ulcerations (see Figures 13.9-3 and 13.9-4). One also may observe significant edema or hyperemia. Determining whether an underlying disease, such as infection, neoplasia, esophageal strictures, or diverticula, is present is important. In addition, one must examine the stomach to determine whether the esophagitis is associated with gastritis, gastric obstruction, or gastric ulcer disease. Contrast radiography may be helpful to detect esophageal ulceration and is useful to assess esophageal motility and transit time.[14]

13.9.3.2 TREATMENT

The principles of therapy for reflux esophagitis include control of gastric acidity, mucosal protection, and correction of any underlying disorder contributing to gastroesophageal reflux. Reduction of gastric acid production with H_2 histamine receptor blockers such as ranitidine or proton pump antagonists such as omeprazole is critical for resolution of the esophagitis. Some clinicians advocate using sucralfate to promote healing of ulcerated esophageal mucosa. However, the ability of sucralfate to bind ulcerated esophageal mucosa is not proven, nor is the efficacy of sucralfate for hastening esophageal ulcer healing.

Horses with reflux esophagitis following delayed gastric outflow caused by gastroduodenal ulcer disease, gastric paresis, or proximal enteritis may benefit from prokinetic drugs that act on the proximal gastrointestinal tract. Metoclopramide (0.02 to 0.1 mg/kg subcutaneously every 4 to 12 hours) reduces gastroesophageal reflux by increasing lower esophageal sphincter tone, gastric emptying, and gastroduodenal coordination. One should exercise caution when giving metoclopramide to horses because they are prone to extrapyramidal neurologic side effects of the drug. Cholinergic drugs such as bethanechol (0.025 to 0.035 mg/kg subcutaneously every 4 to 24 hours or 0.035 to 0.045 mg/kg orally every 6 to 8 hours) may improve gastric emptying and are effective for treating reflux esophagitis. For esophagitis from trauma or pressure injury after esophageal impaction, judicious use of NSAIDs may be warranted to reduce esophageal inflammation and pain.

Dietary modification may be necessary for patients with esophagitis, depending on the degree of ulceration or if motility is impaired. One should feed horses with mild esophagitis frequent small meals of moistened pellets and fresh grass. Severe esophagitis may necessitate withholding food and complete esophageal rest for several 859
days. Although the prognosis for esophagitis is good in the absence of underlying disease, the risk of stricture 860
formation is high if severe circumferential or coalescing ulcerations are present. Esophagitis from severe trauma or infection may be prone to stricture formation.

13.9.4 Motility Disorders

Motility dysfunction of the equine esophagus is caused most commonly by hypomotility resulting in esophageal dilation (ectasia) or megaesophagus. Although megaesophagus in horses most commonly is acquired, reports indicate idiopathic megaesophagus in young horses may be congenital.[28–31] Acquired megaesophagus in horses may be a consequence of chronic or recurrent esophageal obstruction.[3,7] Esophageal impactions of a short duration cause a proximal dilation of the esophagus that is generally reversible.[14] However, if the duration of the obstruction is long enough, the motility of the esophagus proximal to the site of obstruction may be impaired permanently. Other causes of acquired megaesophagus include extraesophageal obstruction by tumors or abscesses, pleuropneumonia, and vascular ring anomalies.[3,8]

Acquired megaesophagus also may result from neurologic, neuromuscular, and muscular disorders. Neurologic diseases that cause vagal neuropathy—such as equine protozoal myeloencephalitis, equine herpesvirus myeloencephalitis, and idiopathic vagal neuropathy—have been associated with megaesophagus in horses. Pleuropneumonia may be associated with a vagal neuropathy resulting in megaesophagus. Megaesophagus is an early sign of equine dysautonomia[32] and may be observable in patients with botulism. Myasthenia gravis is a well-known cause of megaesophagus in nonequine species but has not been reported in horses. Also in other species, electrolyte disorders, cachexia, primary myopathies, myositis, and Addison's disease may affect esophageal motility but have not been associated with megaesophagus in horses. One can induce iatrogenic megaesophagus by the α_2-adrenergic agonist detomidine, but this is transient and reversible.[17,33] Nonetheless, the use of this drug may complicate clinical evaluation of esophageal motility.

Esophageal inflammation, particularly reflux esophagitis, may affect motility and cause megaesophagus. However, because esophageal hypomotility affects the tone and function of the lower esophageal sphincter, reflux esophagitis also may be a complication of a primary functional disorder. Thus assessing esophageal motility in horses with esophagitis that is not responding appropriately to treatment is important.

13.9.4.1 CLINICAL SIGNS AND DIAGNOSIS

Along with a complete physical examination one should include a careful neurologic examination to help rule out primary neurologic causes of megaesophagus. Because esophageal hypomotility is a functional obstruction, the clinical signs of esophageal hypomotility or megaesophagus are similar to esophageal obstruction. Unlike mechanical obstruction the onset of clinical signs is insidious rather than acute. The clinical signs include those associated with esophageal dysphagia.[7,8,28–31] The cervical esophagus may be dilated enough to be evident externally. Weight loss is a common sign. Signs attributable to an underlying disease may be evident.

Diagnosis of esophageal hypomotility requires transit studies. One can measure the transit time of a bolus from the cervical esophagus to the stomach by fluoroscopy or contrast radiography.[14,32] Other signs of esophageal hypomotility and megaesophagus include pooling of contrast material and an absence of peristaltic constrictions.[7,14,28,32] Endoscopy may reveal a dilated esophagus and an absence of peristaltic waves.[7,28] One may observe evidence of underlying disease causing obstruction or esophageal dilation.[3,7] One should evaluate the esophagus for evidence of esophagitis that is causing esophageal motility dysfunction or is a result of impaired esophageal clearance of gastric fluid. Esophageal manometry may be useful to document abnormal postdeglutition contraction pressures, contraction time, and propagation times but is not often available for routine clinical application.[28,34] One should perform other diagnostic tests such as a complete blood count and chemistry to help determine a possible underlying cause. Cerebral spinal fluid analysis may be indicated to rule out neurologic disorders. Specialized testing such as electromyography to detect neuromuscular disorders may also be indicated.

13.9.4.2 TREATMENT

Treatment of esophageal hypomotility or megaesophagus should aim at treating the underlying cause. Dietary modification should aim at improving esophageal transit of food. One should feed the horse slurries of pellets, and feeding from an elevated position to promote transit may be beneficial. Metoclopramide or bethanechol may benefit patients with reflux esophagitis associated with megaesophagus by increasing lower esophageal

tone, gastric emptying, and reducing gastroesophageal reflux. The prognosis depends on the underlying cause and the degree of dilation. Although many cases of megaesophagus associated with reflux esophagitis respond well to treatment, many other forms of megaesophagus including congenital megaesophagus have a poor prognosis.

13.9.5 Esophageal Stricture

Strictures most commonly are caused by pressure necrosis from esophageal impactions that induce circumferential erosion or ulceration of the esophageal mucosa, although esophageal injury caused by oral administration of corrosive medicinal agents and trauma to the neck may also result in stricture formation.[35] Congenital strictures also have been reported.[36] Strictures caused by mucosal and submucosal trauma are termed *esophageal webs* or *rings*. Strictures may also originate in the muscular layers and adventitia of the esophagus (mural strictures) or in all of the layers of the esophagus (annular stenosis).[36,37] Horses with these lesions have a presentation similar to those with simple obstructions, because strictures result in partial obstruction and impaction of food material in the lumen. One can detect esophageal webs or rings with endoscopy (see Figure 13.9-1), whereas identification of mural strictures or annular stenosis may require a double-contrast esophogram (see Figure 13.9-2).

860
861

In a retrospective study of horses with esophageal stricture following simple obstruction, maximal reduction in esophageal lumen diameter occurred within 30 days of the esophageal obstruction. Although surgery has been used to relieve such strictures, initial medical management is warranted because strictures may resolve with conservative therapy, and the esophagus continues to remodel for up to 60 days following ulceration. In one report, seven horses with esophageal obstruction-induced stricture were treated conservatively by feeding a slurry diet and administering antiinflammatory and antimicrobial medications, and five of seven were clinically normal within 60 days.[35] One of the five successfully treated horses had a 10-cm area of circumferential ulceration, suggesting that the potential exists for extensive mucosal injury to resolve without permanent stricture formation.

If resolution of strictures within 60 days is insufficient, one should investigate other methods to increase esophageal diameter. Bougienage has been used successfully in small animal patients and human beings. The technique involves passage of a tubular dilatable instrument down the esophagus and stretching of the stricture. One may perform the technique by passing a nasogastric tube with an inflatable cuff. However, one has to perform the procedure frequently to have any success, and horses do not tolerate it well.[36] Alternatively, a number of surgical techniques have been used to resolve strictures, including resection and anastomosis,[38,39] temporary esophagostomy with fenestration of the stricture,[37] esophagomyotomy for strictures of the muscularis and adventitia,[40,41] or patch grafting with local musculature.[42] However, such surgeries are fraught with complications, largely because of the propensity of the traumatized esophagus to restricture.[3,35] The esophagus lacks a serosal layer and does not rapidly form a fibrin seal as does the remainder of the intestinal tract, so anastomoses tend to leak.[38] In addition, tension on the esophagus during swallowing and movement of the neck impairs healing of anastomoses.[37,39] In spite of these difficulties, the long-term prognosis for horses with chronic esophageal strictures treated surgically is better than for those treated nonsurgically.[3]

13.9.6 Esophageal Diverticula

Two types of diverticula are traction (true) diverticula and pulsion (false) diverticula. Traction diverticula result from wounding and subsequent contraction of periesophageal tissues, with resultant tenting of the wall of the esophagus. Pulsion diverticula arise from protrusion of esophageal mucosa through defects in the muscular wall of the esophagus and usually result from trauma or acute changes in intraluminal pressure.[36] Traction diverticula appear as a dilation with a broad neck on contrast esophagography, whereas pulsion diverticula typically have a flask shape with a small neck on an esophagram (see Figure 13.9-2).[10,43] Although traction diverticula are usually asymptomatic and of little clinical significance, pulsion diverticula may fill with feed material, ultimately leading to esophageal obstruction.[43–45] A movable mass in the midcervical region may be noticeable before onset of complete obstruction.[36] Pulsion diverticula may be corrected surgically by inverting or resecting prolapsed mucosa and closing the defect in the wall of the esophagus.[10,43,45] Inversion of excessive mucosa may reduce the diameter of the esophageal lumen and predispose horses to esophageal obstruction and therefore should be reserved for small diverticula.[10]

13.9.7 Congenital Disorders

Congenital disorders of the esophagus are rare. Reported congenital abnormalities include congenital stenosis,[46] persistent right aortic arch,[8] esophageal duplication cysts,[47–49] intramural inclusion cysts,[9,50] and idiopathic megaesophagus.[28,30,31] In the one report of congenital stenosis, double-contrast radiography revealed concentric narrowing of the thoracic esophagus in the absence of any vascular abnormalities at the base of the heart. Successful treatment included having the foal stand with the forelimbs elevated off the ground following each feeding.[46]

Persistent right aortic arch is a congenital anomaly in which the right fourth aortic arch becomes the definitive aorta instead of the left aortic arch, which results in constriction of the esophagus by the ligamentum arteriosum as it extends between the anomalous right aorta and the left pulmonary artery. Clinical signs may include those associated with esophageal (postpharyngeal) dysphagia, drooling, and distention of the cervical esophagus resulting from partial obstruction of the thoracic esophagus.[8,51] Endoscopic examination typically reveals 861
dilation of the esophagus cranial to the obstruction with evidence of diffuse esophagitis. Successful surgical 862
treatment of persistent right aortic arch has been reported in one foal.[51]

Esophageal duplication cysts and intramural inclusion cysts cause typical signs of esophageal obstruction, including salivation, esophageal dysphagia, and swelling of the cervical esophagus as the cysts enlarge.[47,49,50] Such signs can make them difficult to differentiate from other forms of esophageal obstruction (choke). Endoscopic examination may reveal compression of the esophageal lumen and communication with the esophageal lumen if it exists. Ultrasonographic examination may be the most useful method of antemortem diagnosis if the cyst is in the cervical esophagus. Examination of an aspirate of the mass may aid in the diagnosis by revealing the presence of keratinized squamous cells.[47,50] Surgical treatments have included complete surgical resection and surgical marsupialization.[47,49,50] The latter appears to be more successful and results in fewer complications.[49,50] Complications of surgical resection have included laryngeal hemiplegia following surgical trauma to the recurrent laryngeal nerve in the region of the esophagus and esophageal fistula formation.[50]

13.9.7.1 ESOPHAGEAL PERFORATION

Perforation typically occurs in the cervical region in response to external trauma, necrosis of the esophageal wall caused by a food impaction, or rupture of an esophageal lesion such as an impacted diverticulum. The esophagus is particularly vulnerable to external trauma in the distal third of the neck because only a thin layer of muscle covers it at this point.[52] Iatrogenic perforation may occur in response to excessive force with a stomach tube against an obstruction or a compromised region of the esophagus.[24] Esophageal perforations may be open or closed and tend to cause extensive cellulitis and necrosis of tissues surrounding the wound because of drainage of saliva and feed material within fascial planes. Systemic inflammation associated with endotoxemia from septic cellulitis may occur. Closed perforations of the esophagus are particularly troublesome because food material, water, saliva, and air may migrate to the mediastinum and pleural space via fascial planes.[24,52] Because of the leakage of air into the tissues surrounding the rupture, extensive subcutaneous and fascial emphysema frequently develops and is usually evident clinically and on cervical radiographs. Pneumomediastinum and pneumothorax are potentially fatal complications of esophageal ruptures.

Treatment should include converting closed perforations to open perforations if possible,[53] extensive debridement and lavage of affected tissues, broad-spectrum antibiotics, tetanus prophylaxis, and esophageal rest. The clinician may achieve the latter by placing a feeding tube into the esophagus via the wound. Alternatively, one may place a nasogastric tube using a small tube (12-F diameter).[24] For open perforations, once the wound has granulated and contracted to a small size, one may attempt peroral feeding.[52] Extensive loss of saliva via esophageal wounds may lead to hyponatremia and hypochloremia. In addition, transient metabolic acidosis occurs because of salivary bicarbonate loss, followed by progressive metabolic alkalosis.[21] Although reports of esophageal wounds healing well by second intention exist, healing takes a prolonged time.[54] In addition, some perforations never completely heal and form permanent esophagocutaneous fistulae that may require surgical correction. The development of esophageal strictures is not common because wounds are usually linear and not circumferential. However, traction diverticula may develop. Other complications of esophageal wounds include Horner's syndrome and left laryngeal hemiplegia.[52]

In a retrospective study on esophageal disorders, only 2 of 11 horses with esophageal perforations survived long-term[3]; in a report of esophageal trauma following nasogastric intubation, 4 of 5 horses were euthanized.[24] The prognosis is therefore poor in horses with esophageal perforations, largely because of the extent of cellulitis, tissue necrosis, shock, and local wound complications.

13.10 13.10—Diseases of the Stomach

L. Chris Sanchez

Specialized endoscopic equipment allowing visual inspection of the entire adult equine stomach has become 863
increasingly available to veterinarians in academia and private practice. Thus gastric disease in horses recently has 864
gained increasing awareness among veterinarians, owners, and trainers.

13.10.1 Gastroduodenal Ulceration

Peptic ulcer disease is defined as erosions or ulcers of any portion of the gastrointestinal tract normally exposed to acid.[1] Mucosal damage can include inflammation, erosion (disruption of the superficial mucosa), or ulceration (penetration of the submucosa). In severe cases, full-thickness ulceration can occur, resulting in perforation. The proximal (orad) portion of the equine stomach is lined by stratified squamous mucosa similar to the esophageal lining. The distal (aborad) portion of the stomach is lined with glandular mucosa, and the distinct junction between the two regions is deemed the *margo plicatus*. Ulceration can occur in either or both gastric regions, although different clinical syndromes and pathophysiologic mechanisms apply. As a result, the broad term *equine gastric ulcer syndrome* (EGUS) has been used to encompass the wide array of associated clinical syndromes. EGUS develops in horses of all ages and continues to be of major clinical and economical importance.[2]

13.10.1.1 PREVALENCE

The prevalence of gastric ulceration has been reported for a variety of breeds and types of horses; however, most current data involve Thoroughbreds in race training. The prevalence of squamous ulceration in horses in race training varies from 70% to 94%[3–8] and can be as high as 100% when limited to animals actively racing.[4] In a survey of 50 active show horses, 58% had gastric ulceration, with only 1 horse having ulceration of the glandular fundus.[9] In one large retrospective study (3715 adult horses from 1924 to 1996) evaluating

incidence of gastric ulceration identified at necropsy, an overall prevalence of 10.3% was found. The highest prevalence was found in Thoroughbreds (including Arabians) and Standardbred trotters, and cold-blooded horses were affected significantly less. Lesions were located most commonly in the squamous mucosa along the margo plicatus, followed by the glandular body, proximal squamous mucosa, and antrum.[10]

Many studies investigating prevalence of gastric ulceration do not differentiate between squamous and glandular lesions or evaluate only squamous disease. In a recent study in which the gastric antrum and pylorus were evaluated in 162 horses in a hospital setting, 58% had antral or pyloric erosions or ulcerations, 58% had squamous mucosal lesions, and 8% had lesions involving the glandular body.[11] A correlation between the presence or severity of squamous disease and antral/pyloric disease was not identified.

The reported prevalence of gastric ulceration in foals varies from 25% to 57%.[12–14]

13.10.1.2 PATHOPHYSIOLOGY

An imbalance between inciting and protective factors in the mucosal environment can result in ulcer formation.[15,16] The major intrinsic factors promoting ulcer formation include hydrochloric acid, bile acids, and pepsin, with hydrochloric acid being the predominant factor. Various intrinsic factors protect against ulcer formation such as the mucus-bicarbonate layer, maintenance of adequate mucosal blood flow, mucosal prostaglandin E_2 and epidermal growth factor production, and gastroduodenal motility. In human beings, extrinsic ulcerogenic factors include nonsteroidal antiinflammatory drugs, *Helicobacter pylori,* stress, changes in diet, or gastrointestinal disorders, especially those resulting in delayed gastric emptying.[1] In human neonates, physiologic stress associated with a major primary illness seems to be associated strongly with gastric ulcers.[17] Many of the other factors mentioned previously are believed to be important in horses, but clear evidence of an infectious agent has not yet been identified in horses or foals with EGUS.[18,19] Recently, the possibility of *Helicobacter* infection in horses has reemerged with the identification of polymerase chain reaction products from Urel, a proton-gated urea channel unique to gastric-dwelling *Helicobacter* species, in the squamous epithelium of three horses, two of which had squamous erosions.[20]

The specific factors involved in injury and the protective mechanisms vary between regions of the proximal gastrointestinal tract. The pathophysiology of squamous mucosal ulceration in the horse appears similar to that in gastroesophageal reflux disease in human beings and ulceration of the nonglandular mucosa in pigs. Excess acid exposure is the predominant mechanism responsible for squamous mucosal ulceration, although many details remain unclear.[21] Hydrochloric acid is secreted by parietal cells in the gastric glands via a hydrogen-potassium adenosine triphosphatase (H^+,K^+-ATPase) pump on the luminal side. Horses secrete acid continuously, and measured pH of equine gastric contents varies from less than 2 to greater than 6 depending on the dietary state of the horse (fed or fasted).[22,23] A protocol of repeated 24-hour periods of fasting and feeding has been shown to induce squamous erosion and ulceration.[24] Because this protocol results in periods of prolonged gastric acidity (pH <2.0) and because concurrent administration of the histamine$_2$ (H_2) receptor antagonist ranitidine reduces lesion severity, the protocol supports the role of acid exposure in the pathogenesis of squamous ulcer disease.

Several peptides can stimulate or inhibit parietal cell secretion of acid. The predominant stimuli for hydrochloric acid secretion are gastrin, histamine, and acetylcholine via the vagus nerve.[1] G cells release gastrin within the antral mucosa, whereas mast cells and enterochromaffin-like cells release histamine in the 864

gastric gland. Histamine binds to type 2 receptors on the parietal cell membrane, causing an increase in cyclic adenosine monophosphate and resulting in phosphorylation of enzymes that activate the proton pump. Gastrin and acetylcholine can act via calcium-mediated intracellular pathways and also stimulate histamine release directly.[25] Isolated equine parietal cells respond maximally to histamine stimulation and only minimally to carbachol and pentagastrin.[26] Gastrin release is controlled primarily by gastrin-releasing peptide, which is stimulated by gastric distention and increased luminal pH, but the interaction between gastrin and histamine has not been elucidated fully in the horse. 865

Somatostatin, released by fundic and antral D cells, is the primary inhibitor of gastric acid secretion by parietal cells. The inhibitory effect of somatostatin is primarily paracrine, but plasma levels of somatostatin negatively correlate with gastric luminal acidity.[27] Epidermal growth factor, a peptide produced in saliva, also inhibits gastric acid secretion.[28]

Foals can produce significant amounts of gastric acid by the second day of life, with consistent periods of acidity (pH <2.0) in clinically normal animals.[29,30] In one study, foals tended to have a high gastric pH at day 1 of age,[30] but in a study of critically ill foals, some foals demonstrated periods of gastric acidity on the first day of life.[31] Suckling was associated with an immediate rise in gastric pH, whereas periods of rest in which foals did not suck for more than 20 minutes were associated with prolonged periods of acidity.[29] Whereas premature human infants are capable of gastric acid production at 28 weeks of gestation,[32] only 1 of 7 premature foals demonstrated an acidic pH recording in a study of gastric pH profiles in critically ill foals.[31] However, multiple factors likely were involved in critically ill foals of this study, and the true ontogeny of gastric acid production in foals is currently unknown.

Equine squamous mucosa is thin at birth but becomes hyperplastic and parakeratotic within days.[33] The parallel between decreasing pH and proliferation of squamous epithelium correlates with that observed in other species.[34] The combination of a thin gastric epithelium with a high acid output may leave neonatal foals susceptible to ulcer formation at a young age. In addition, one must remember the difference in normal appearance of the squamous mucosa when interpreting gastric endoscopy in a neonatal population.

In esophageal squamous mucosa, intercellular tight junctions and bicarbonate secretion are the major factors involved in protection against acid injury in other species, although squamous bicarbonate secretion had not been documented in the horse.[35–37] The principal barrier is a glycoconjugate substance secreted by cells in the *stratum spinosum,* with a contribution from the tight junctions in the *stratum corneum*.[37] This barrier function is considered weak at best, and thus a functioning lower esophageal sphincter, normal salivary flow, and salivary mucins contribute to the prevention of acid injury in human gastroesophageal reflux disease. In horses a mechanical barrier like the lower esophageal sphincter is not available to protect the gastric squamous mucosa from acid exposure. The normal gastric fill line rests just below the cardia, so only the squamous mucosa along the lesser curvature adjacent to the margo plicatus should receive exposure to acidic gastric contents regularly. Not surprisingly, this correlates with the most common location of squamous mucosal ulceration.

Bile salts and pepsin have been implicated as contributing factors to ulcer disease in many species. In rabbit esophageal mucosa, bile salt absorption occurs and is correlated directly with mucosal barrier disruption. The unconjugated bile salts cholate and deoxycholate have a pK_a (negative logarithm of the ionization constant of an acid) of 5 and 5.3, respectively, and therefore cannot remain in solution and cause mucosal damage in the presence of acid. Alternatively, the conjugated bile salt taurocholate (pK_a 1.9) can cause mucosal injury in the

ionized salt form at pH 7 or the un-ionized acid form at pH 1 to 2.[38] In the pig, bile salts or acid alone cause squamous mucosal damage, whereas a combination of the two result in extensive damage in vitro.[39] In the horse a similar synergistically damaging effect was found with the addition of bile salts and acid (pH 2.5) to stratified squamous mucosa in vitro in one study.[40] In addition, the investigators were able to document levels of bile salts and acid sufficient to cause mucosal damage in gastric contents within 14 hours of feed deprivation. This is not surprising, given that duodenogastric reflux occurs normally in the horse.[41] In a separate in vitro study of equine squamous mucosa, prolonged exposure to acid alone (pH 1.5) had a damaging effect, and synergism with exposure to a combination of acid and pepsin or taurocholate was not found.[42] The lack of synergism likely is caused by the lower pH used in this study and stresses the importance of acid exposure in squamous ulcer disease.

Pepsinogens are secreted primarily by chief cells, although secretion by neck cells, cardiac glands, and antral pyloric glands also occurs.[43] In an acidic environment (pH <3.0), pepsinogen is converted to the active pepsin. Although the proteolytic activity of pepsin normally is directed toward dietary protein, it also can act on the gastric mucosa.[44] Thus acid remains the major contributing factor to squamous mucosal damage, although other factors such as pepsin and bile salts may play an important role as well in the initiation or perpetuation of disease.

865

866

Several mechanisms help protect the glandular mucosa from acid injury. The mucus-bicarbonate layer serves to titrate H^+ ion from the gastric lumen to CO_2 and H_2O. Cellular restitution and prostaglandins of the E series, which enhance mucosal blood flow and secretion of mucus and bicarbonate in the glandular mucosa have not been documented in squamous epithelium.[21,36] Of these mechanisms, mucosal blood flow is likely the most important contributor to overall gastric mucosal health. Nitric oxide is a key regulator of mucosal blood flow and prostaglandin synthesis and thus may play a role in mucosal protection.[45]

Dietary factors also have been implicated in ulcer disease. Horses in race training have a high incidence of gastric ulceration and frequently are fed high-concentrate, low-roughage diets. In one study, higher volatile fatty acid (acetic, propionic, and isovaleric acid) concentrations, higher gastric juice pH, and lower number and severity of nonglandular ulceration were documented after feeding an alfalfa hay-grain diet compared with a bromegrass hay diet.[46] However, many factors differed between the diets, such as digestible energy, bulk, crude protein, and mineral content (especially calcium). Thus dietary factors represent an important area of further investigation in the pathophysiology of EGUS, particularly squamous ulceration.

The pathophysiologic correlation between exercise and squamous ulcer disease has not yet been defined despite the high prevalence of ulceration in performance horses. Preliminary work suggests that gastric compression occurs during treadmill exercise, presumably because of an increase in intraabdominal pressure.[47] Such contracture could result in increased acid exposure to the squamous mucosa by raising the fill line of gastric contents. Further studies in this laboratory have provided support for this theory by demonstrating a high pH in the proximal stomach, immediately distal to the lower esophageal sphincter, during resting conditions that decreases during treadmill exercise (M. Lorenzo-Figueras and A.M. Merritt, personal communication, 2002).

Risk factors associated with gastric ulceration include gender and age, and the reported prevalence of gastric ulcers has increased over time. In one study, ulcers were found more commonly in stallions, and the prevalence of gastric ulceration decreased with age, independent of gender, although this trend was only significant in the population of Standardbred trotters.[10] Interestingly, the frequency of gastric ulceration

increased from less than 6% before 1945 to approximately 18% after 1975. In a study of Thoroughbred horses in race training, an increase in squamous ulcer severity was noted in horses 3 years old or older and in those horses that had raced.[4] In the same study, severity of glandular lesions did not change between examinations, and age (>3 years) was the only factor associated with glandular lesion severity.

Several studies have failed to document a correlation between nonsteroidal antiinflammatory drug (NSAID) administration and naturally occurring ulcer disease.[3,4,6,7,10] However, NSAID administration is a well-known cause of gastric ulceration under experimental conditions.[48–52] NSAID-related ulceration typically is described as predominantly glandular, although nonglandular ulceration also can occur by a mechanism that has not yet been characterized fully. NSAIDS cause a decrease in prostaglandin E_2 synthesis because of inhibition of the cyclooxygenase pathway. Therefore a resultant decrease in glandular mucosal protection, most notably via decreased mucosal blood flow and mucus production, is the most likely mechanism of action. In one study, however, phenylbutazone administration resulted in ulceration of the glandular mucosa at the pyloric antrum but did not alter mucosal prostaglandin E_2 concentration significantly.[52]

13.10.1.3 CLINICAL SYNDROME: NEONATAL FOALS

Clinical signs typically associated with gastric ulceration in foals include poor appetite, diarrhea, and colic. Many foals probably never exhibit clinical signs, and some do not exhibit clinical signs until ulceration is severe or fatal perforation has occurred. Glandular ulceration typically is considered the most clinically significant type of disease in this population.

The physiologic stress of a concurrent illness has been associated with gastric ulceration in foals. Retrospectively, 14 (23%) of 61 foals up to 85 days of age with a clinical disorder were found to have lesions in the gastric glandular mucosa,[13] and prospectively 8 (40%) of 20 foals up to 30 days of age with a clinical disorder had glandular ulceration.[53] By contrast, only 4% to 9% of clinically normal foals examined in endoscopic surveys had lesions observed in the gastric glandular mucosa.[14,54]

Critically ill neonatal foals can have a greatly different pH profile compared with that in clinically normal foals, potentially because of alterations in gastric motility and acid secretion.[31] Gastric ulceration was not identified in any animals at necropsy in that study; however, ulceration has been documented in a similar population.[12] Thus factors other than acid exposure, most notably mucosal blood flow, may play an important role in the stress-related ulceration in neonates. Subjectively, gastric ulceration and rupture in the hospitalized neonatal population occurs less commonly now than in previous reports. Advances in overall neonatal care, especially supportive care, likely have contributed to this decline.

13.10.1.4 CLINICAL SYNDROME: SUCKLINGS/WEANLINGS

In suckling foals less than 50 days old, lesions typically originate in the squamous mucosa adjacent to the margo plicatus along the greater curvature. Such lesions can occur in foals as young as 2 days of age and have 866
been observed in 50% of foals less than 50 days old. Histologic examination of these lesions has revealed 867
disruption of the epithelial layers of the mucosa and a neutrophilic infiltration. Another phenomenon that occurs in young foals is the shedding, or desquamation, of squamous epithelium, which appears as flakes or sheets of epithelium. Desquamation occurs without ulceration in up to 80% of foals less than 35 days of age, and this process typically is not associated with clinical signs.[13,14,54]

In older foals, lesions become more prevalent in the squamous mucosa, particularly along the lesser curvature.[53] Lesions also are found in the squamous mucosa of the fundus and adjacent to the margo plicatus. These lesions can be severe and often are associated with clinical signs such as diarrhea, poor appetite, and poor growth and body condition. Diarrhea is the most frequent sign in symptomatic foals with squamous mucosal lesions and is associated with more diffuse erosion or ulceration of the squamous mucosa than that which occurs in asymptomatic foals. In some foals, poor growth, rough hair coat, a potbelly appearance, or all of those occur along with moderate to severe squamous mucosal ulceration. In horses with severe or diffuse squamous ulceration, bruxism or colic may occur.

Gastroduodenal ulcer disease occurs almost exclusively in suckling and early weanling foals. Clinical signs of duodenal ulceration are similar to those described for gastric ulceration (bruxism, colic, salivation, diarrhea), but the consequences are often more severe. Lesions occur primarily in the proximal duodenum and range from diffuse inflammation to severe ulceration. Foals with duodenal ulceration often have delayed gastric emptying and may have gastroesophageal reflux. Complications can include gastric or duodenal rupture, duodenal stricture, and ascending cholangitis. Severe squamous and esophageal ulceration and aspiration pneumonia can occur following gastroesophageal reflux.[15,55–58]

The gastroduodenal ulcer disease syndrome can occur in outbreaks and most commonly is identified in intensive breeding operations. The cause of duodenal lesions in foals is not known. One theory is that the problem begins with diffuse duodenal inflammation that can coalesce down to a focal area of ulceration (G.D. Lester and A.M. Merritt, personal communication, 2002). A temporal relationship between gastroduodenal ulcer disease and rotaviral diarrhea has been suggested, but an infectious cause remains unproven. Although lesion location and severity associated with rotaviral infection varies among species, duodenal ulceration has not been reported.[59]

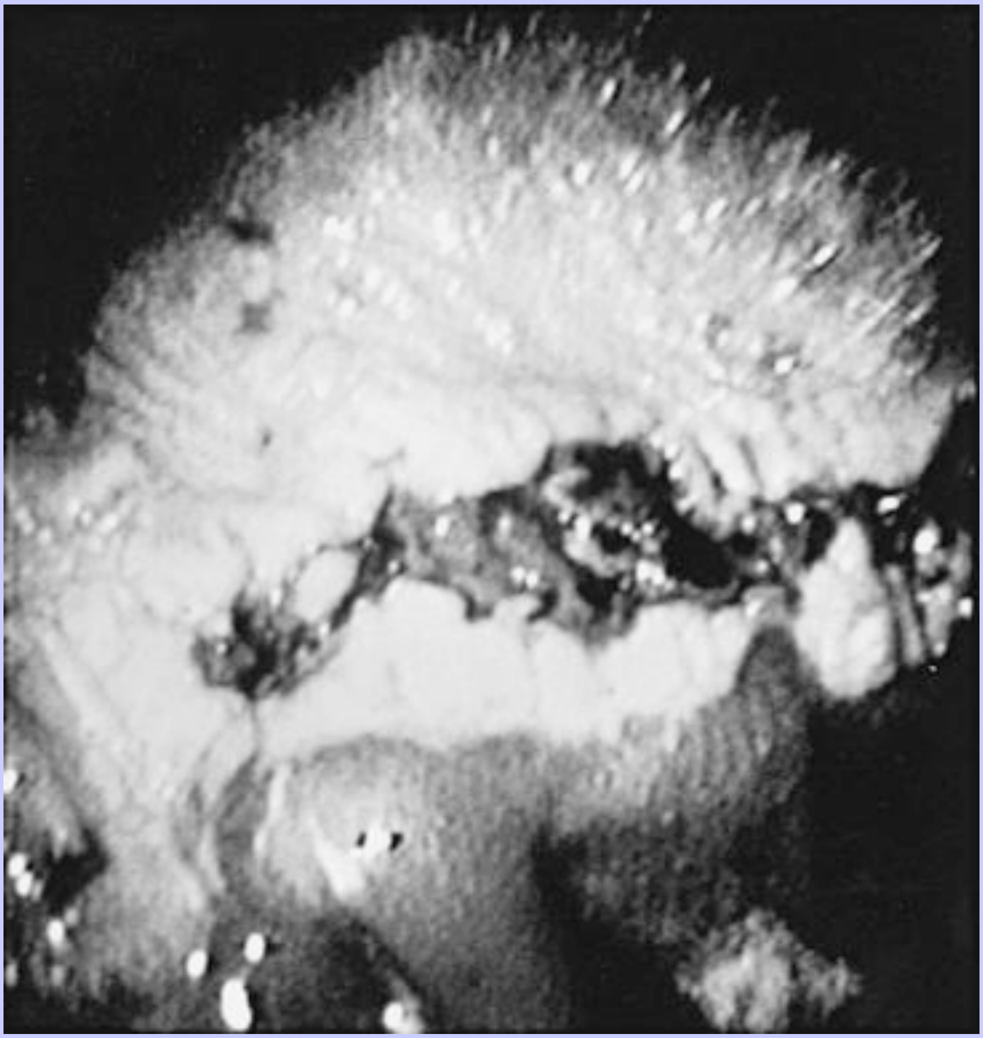
13.10.1.5 CLINICAL SYNDROME: YEARLINGS AND ADULT HORSES

Clinical signs attributable to EGUS in older horses vary and classically include anorexia and chronic or intermittent colic of varying severity.[60] Many horses with endoscopic evidence of disease may appear to be clinically normal or have vague signs that include decreased consumption of concentrates, postprandial episodes of colic, poor performance or failure to train up to expectations, poor-quality hair coat, and decreased condition or failure to thrive. Diarrhea typically is not associated with gastric ulceration in adult horses, although ulceration can occur concurrently with other causes of diarrhea. Horses actively racing are more likely to have squamous ulceration than those solely in training.[4]

Lesions occur predominantly in the squamous mucosa, particularly adjacent to the margo plicatus (Figure 13.10-1). In more severe cases, lesions can extend dorsally into the squamous fundus. Clinically relevant lesions typically affect a greater portion of the squamous mucosa and can be deep enough to cause bleeding. However, bleeding from ulcers in the gastric squamous mucosa typically is not associated with anemia or hypoproteinemia.

According to a recent study, the incidence of glandular lesions, particularly within the pyloric region, may be higher than previously reported,[11] which emphasizes the importance of a thorough endoscopic examination and proper documentation of lesion location when reporting or discussing EGUS, especially the differentiation between squamous and glandular disease.

Figure 13.10-1 Endoscopic view of the right side of the stomach of a horse with recurrent colic and poor appetite. The large area of ulceration on the squamous mucosa adjacent to the margo plicatus is notable.



867

TABLE 13.10-1 Equine Gastric Ulcer Syndrome Lesion Scoring System

LESION GRADE	DESCRIPTION
0	Intact epithelium with no appearance of hyperemia or hyperkeratosis
1	Intact mucosa with areas of reddening or hyperkeratosis (squamous)
2	Small single or multifocal lesions
3	Large single or multifocal lesions or extensive superficial lesions
4	Extensive lesions with areas of deep ulceration

From Andrews FM, Bernard WV, Byars TD et al: Recommendations for the diagnosis and treatment of equine gastric ulcer syndrome (EGUS), *Equine Vet Educ* 1:122–134, 1999.

13.10.1.6 DIAGNOSIS

Although one may suspect a diagnosis of EGUS based on clinical signs and response to treatment, the only current method of confirmation is via gastroendoscopy, which one can perform easily in the standing horse or foal with mild sedation. In adult horses a 3-m endoscope allows for visual inspection of the entire stomach, pylorus, and proximal duodenum. Shorter scopes permit examination of the gastric body and fundus, but not the pyloric antrum in most cases. One should use an endoscope with a maximum external diameter of 9 mm for neonatal foals. Numerous scoring systems for lesion severity have been described, but a recent consensus has been published by the Equine Gastric Ulcer Council (Table 13.10-1).[2]

Duodenal ulceration can be difficult to confirm. Duodenoscopy is the most specific means of diagnosis, although the procedure is more difficult than gastroscopy. Additionally, an endoscope at least 200 cm in length is needed for foals up to 5 to 7 months old, and a longer endoscope usually is required for older animals. Diffuse reddening or inflammation may be the only recognizable lesion in cases of early duodenal disease.

Excessive enterogastric reflux of bile through the pylorus suggests duodenal dysfunction. However, the pylorus frequently appears open, and some degree of enterogastric reflux is common under normal conditions. Ulceration at the pylorus or pyloric antrum also suggests the presence of a duodenal lesion. If one can perform gastroendoscopy, but not duodenoscopy, the severity of lesions, particularly in the glandular mucosa and in the squamous mucosa of the lesser curvature dorsal to the pyloric antrum, usually will be severe when duodenal ulcers are present.

TABLE 13.10-2 Therapeutic Options for Treating Equine Gastric Ulcer Syndrome

DRUG	DOSE (mg/kg)	DOSING INTERVAL (HOURS)	ROUTE OF ADMINISTRATION
Ranitidine	6.6	8	Orally
Ranitidine	1.5–2	6–8	Intravenously or intramuscularly
Cimetidine	20–25	8	Orally
Cimetidine	6.6	6–8	Intravenously or intramuscularly
Omeprazole	2–4	24	Orally
Sucralfate	20–40	8	Orally
Aluminum/magnesium antacids	0.5	4	Orally

13.10.1.7

TREATMENT

Multiple pharmacologic treatments have been suggested for treating EGUS. Because acid has been implicated as the most important pathophysiologic component of squamous ulcer disease, most antiulcer therapy centers on suppression or neutralization of gastric acid. Severity and location of gastric lesions and severity and duration of clinical signs, as well as medication cost, can play a role in the therapeutic management of EGUS (Table 13.10-2).

If gastroendoscopy is unavailable, some guidelines to therapy can be used, but the efficacy of the treatment is based on clinical signs, which are often vague or nonspecific. Signs of colic or diarrhea that result from gastric ulcers often resolve within 48 hours. One can note improvements in appetite, bodily condition, and attitude within 1 to 3 weeks. If one does not observe improvement in clinical signs, treatment has not been effective or gastric ulceration was not the primary problem.

The principal therapeutic options for ulcer treatment include H_2 antagonists (cimetidine, ranitidine, famotidine, nizatidine), proton pump blockers (omeprazole, pantoprazole, rabeprazole, esomeprazole), the mucosal adherent sucralfate, and antacids.

The H_2 antagonists suppress hydrochloric acid secretion through competitive inhibition of the parietal cell histamine receptor that can be overcome partially with exogenous pentagastrin.[61] Use of H_2 antagonists has been successful in raising gastric pH and resolving gastric lesions in foals and adult horses.[29,55,62]

Clinical and experimental evidence has demonstrated greater individual variability with lower dosages of H_2 antagonists.[63] Thus dosage recommendations are based on levels necessary to increase gastric pH and promote ulcer healing in a majority of horses. Commonly recommended dosages are 20 to 30 mg/kg orally every 8 hours or 6.6 mg/kg intravenously every 6 hours for cimetidine and 6.6 mg/kg orally every 8 hours or 1.5 to 2 868 869

mg/kg intravenously every 6 hours for ranitidine. Famotidine has been used less extensively in the horse, but a dose of 10 to 15 mg/kg/day has been recommended.

Because gastric perforation caused by glandular ulcer disease has been reported in hospitalized neonates, many clinicians routinely use prophylactic antiulcer therapy in this population. Although clinically normal foals respond predictably to ranitidine,[29] sick neonates have shown variability in pH response to intravenously administered ranitidine, with a much shorter duration of action and in some cases no noticeable response.[31] Thus currently used dosing schedules for hospitalized foals may be inadequate. Because some critically ill foals have a predominantly alkaline gastric pH profile and because gastric acidity may be protective against bacterial translocation in neonates, the need for prophylactic ulcer therapy is controversial. In critically ill human neonates, intravenous administration of ranitidine raises gastric pH and gastric bacterial colonization but does not increase the risk of sepsis.[64] In a retrospective study of 85 hospitalized foals less than 30 days of age, no difference in the frequency of gastric ulceration at necropsy was found between those foals that received prophylactic treatment for gastric ulcers and those that did not.[65] Because the study was retrospective, specific details regarding lesion location and severity were not available; however, none of the foals in the study died because of gastric ulcer disease.

H_2 antagonist therapy should continue for 14 to 21 days, but complete ulcer healing may take 30 to 40 days. If an animal is kept in race training during therapy, clinical signs may resolve but the lesions may not. Currently, cimetidine and ranitidine are available in injectable, tablet, and liquid forms. Famotidine and nizatidine are available in tablets.

Proton pump inhibitors block secretion of H^+ at the parietal cell membrane by irreversibly binding to the H^+,K^+-ATPase proton pump of the cell. These agents have a prolonged antisecretory effect, which allows for once-daily dosing. Omeprazole, the first proton pump inhibitor to be developed, is the only currently approved agent for the treatment of EGUS.

Several studies have documented the safety of orally administered omeprazole in foals and adult horses.[66,67] Omeprazole has demonstrated efficacy in the healing of NSAID-induced ulcers in horses and in naturally occurring cases of EGUS.[68,69] More importantly, omeprazole has been shown to eliminate or reduce the severity of gastric ulcers in Thoroughbreds maintained in race training.[70]

The available equine preparation of omeprazole (GastroGard, Merial, Ltd., Duluth, Georgia) is recommended at a dose of 4 mg/kg orally every 24 hours. Initial reports suggested that 3 to 5 days of omeprazole therapy were necessary to achieve maximum acid suppression; however, an increase in gastric pH and a decrease in acid output are evident 5 to 8 hours after omeprazole paste administration.[71] After initial treatment (28 days), treatment with 2 or 4 mg/kg every 24 hours has been shown to decrease or prevent the recurrence of disease in animals maintained in training.[72] The powder form of omeprazole degrades rapidly in an acidic environment, thus one must use an enteric-coated capsule (as used in the human preparation) or a specially formulated paste (such as GastroGard) to allow delivery of the active drug to the small intestine for absorption. Many compounding pharmacies prepare omeprazole in liquid or paste formulation for use in horses, but their efficacy has not been evaluated to date.

Other proton pump inhibitors have been developed recently for use in human beings, including rabeprazole, lansoprazole, esomeprazole, and pantoprazole. In gastro esophageal reflux disease treatment in human beings, esomeprazole has demonstrated a higher rate of healing at 4 and 8 weeks compared with omeprazole, but

rabeprazole, lansoprazole, and pantoprazole have similar efficacy.[73] An intravenous formulation of pantoprazole recently became available commercially and may prove beneficial for patients in need of antiulcer therapy that cannot be treated orally. Research regarding the pharmacokinetics and efficacy of other proton pump inhibitors in horses is not currently available.

Sucralfate is effective in treating peptic ulcers and preventing stress-induced ulcers in human beings. The mechanism of action likely involves adherence to ulcerated mucosa, stimulation of mucus secretion, enhanced prostaglandin E synthesis, and increased concentration of growth factor at the site of ulceration, although the prostaglandin effects may not play an important role in ulcer healing.[74] These are factors relevant to glandular mucosa, and the efficacy of sucralfate in treating ulcers in the equine gastric squamous mucosa remains undetermined. Sucralfate may be effective in preventing stress-induced ulcers in neonatal foals, because these occur in the glandular mucosa, although no clinical evidence directly supports this concept. In human beings, sucralfate provides protection against stress-induced ulcers with a decreased risk of pathogenic gastric colonization.[75] One should give sucralfate at a dosage of 10 to 20 mg/kg every 6 to 8 hours. The efficacy of sucralfate in an alkaline pH is controversial but appears likely.[76–78] Moreover, at the time of administration of 869
an H_2 antagonist, the gastric pH likely will have returned to an acidic pH since the last dosage and will remain 870
so for 30 to 60 minutes depending on the route of administration; thus one likely can administer the agents simultaneously if so desired.

The use of antacids to treat gastric ulcers has not been examined critically in the horse. Research in horses has shown that 30 g aluminum hydroxide per 15 g magnesium hydroxide results in an increase in gastric pH above 4 for approximately 2 hours.[79] Thus although antacids may be useful for treating ulcers in horses, a dose of approximately 180 to 200 ml at least every 4 hours is necessary for a standard adult horse.

The use of synthetic prostaglandin E_1 analogs, such as misoprostol, has been effective in treating gastric and duodenal ulcers in human beings, and the proposed mechanism of action involves inhibition of gastric acid secretion and mucosal cytoprotection.[80] Frequently reported adverse effects of intestinal cramping and diarrhea in human beings have precluded the use of misoprostol in horses.

One should consider prokinetic drugs in foals with duodenal disease and gastroesophageal reflux and when one suspects delayed gastric emptying without a physical obstruction. The cholinergic drug bethanechol has been shown to increase the rate of gastric emptying in horses.[81] In cases of acute gastric atony, bethanechol 0.025 to 0.030 mg/kg administered subcutaneously every 3 to 4 hours has been effective in promoting gastric motility and emptying, followed by oral maintenance dosages of 0.35 to 0.45 mg/kg 3 to 4 times daily. Adverse effects can include diarrhea, inappetance, salivation, and colic, but at the dosages stated, adverse effects have been infrequent and mild. A complete review of ileus and prokinetic therapy is available in Chapter 13.6.

For foals with severe gastroduodenal ulcer disease that have developed duodenal stricture, surgical therapy is necessary.[57,82] These animals require a serious financial commitment because intensive perioperative medical therapy is critical for a successful outcome. Even with surgical therapy, these foals often warrant a guarded prognosis.

13.10.2 Other Disorders of the Stomach

13.10.2.1 PYLORIC STENOSIS AND DELAYED GASTRIC EMPTYING

Pyloric stenosis is a structural resistance to gastric outflow. Congenital pyloric stenosis has been reported in foals and one yearling and results from hypertrophy of the pyloric musculature.[83–85] Acquired pyloric stenosis can result from neoplasia or duodenal ulceration.[86–89] Clinical signs depend on the degree of obstruction and include abdominal pain, salivation, and teeth grinding. Complete or near complete obstruction can result in gastric reflux and reflux esophagitis. In foals with congenital pyloric hypertrophy, clinical signs may begin with the consumption of solid feed. In foals one can make a presumptive diagnosis via gastric endoscopy and radiography (plain and contrast studies). Depending on the cause and severity of disease, gastric endoscopy may provide a presumptive diagnosis in the adult horse. Measurement of gastric emptying can aid the diagnosis. Several methods of measurement are currently available, including nuclear scintigraphy, acetaminophen absorption, and postconsumption [^{13}C] octanoic acid blood or breath testing.[81,90,91] Exploratory laparotomy shows a distended stomach and thickened pylorus accompanied by a relatively empty intestinal tract.

If complete obstruction is not present, medical therapy with a prokinetic such as bethanechol can increase the rate of gastric emptying.[81] Phenylbutazone and cisapride also have been shown to attenuate the delay in gastric emptying caused by endotoxin administration.[90,92] Surgical repair is necessary for definitive treatment of complete or near-complete obstruction and consists of gastroenterostomy or pyloroplasty.[57,82]

13.10.2.2 GASTRIC DILATION AND RUPTURE

Gastric dilation can be classified as primary, secondary, or idiopathic. Causes of primary gastric dilation include gastric impaction, grain engorgement, excessive water intake after exercise, aerophagia, and parasitism.[86,93] Secondary gastric dilation occurs more commonly and can result from primary intestinal ileus or small or large intestinal obstruction. Time to development of gastric reflux is proportional to the distance to the intestinal segment involved, with duodenal obstruction resulting in reflux within 4 hours.[94] Clinical signs of gastric dilation include those associated with acute colic and in severe cases, ingesta appearing at the nares. Associated laboratory abnormalities include hemoconcentration, hypokalemia, and hypochloremia.[86]

The most common reported cause of gastric rupture in horses varies between reports. In a retrospective study of 54 horses, gastric rupture occurred most commonly as a secondary phenomenon (65%), usually because of small intestinal obstruction, with primary gastric dilation and idiopathic rupture occurring almost equally (15% and 17%, respectively).[93] In another retrospective study of 50 horses in combination with a search of the Veterinary Medical Database (VMDB), 60% of the gastric rupture cases were classified as idiopathic.[95] Risk factors for gastric rupture include feeding grass hay, not feeding grain, gelding, and a nonautomatic water source.[93,95] Nasogastric intubation does not preclude the possibility of gastric rupture, and the amount of 870
reflux obtained before rupture varies greatly.[93] Because these reports were retrospective, one cannot rule out 871
confounding factors with certainty.

Regardless of the initiating cause, gastric rupture usually occurs along the greater curvature. In horses with rupture caused by gastric dilation, tears in the seromuscular layer are frequently larger than the corresponding

tears in the mucosal layer, indicating that the seromuscularis likely weakens and tears before the mucosa.[93,95] In contrast, horses with gastric rupture following gastric ulceration usually demonstrate full-thickness tears of equal size in all layers. Gastric rupture is usually fatal because of widespread contamination of the peritoneal cavity, septic peritonitis, and septic shock. Initial clinical signs vary with the primary disease; however, when rupture occurs, a previously painful animal can exhibit signs of relief. Subsequent signs are consistent with peritonitis and shock, including tachypnea, tachycardia, sweating, and muscle fasciculations. Surgical repair is thus limited but has been reported for partial-thickness tears,[96] and in one case of a combined tear of the mucosa and muscularis with only a focal serosal tear, a full-thickness repair was performed with a favorable outcome.[97]

13.10.2.3 GASTRIC IMPACTION

Gastric impaction can result in acute or chronic signs of colic in the horse. Although a specific cause is not always evident, ingestion of coarse roughage (straw bedding, poor-quality forage), foreign objects (rubber fencing material), and feed that may swell after ingestion or improper mastication (persimmon seeds, mesquite beans, wheat, barley, sugar beet pulp) have been implicated. Possible predisposing factors include poor dentition, poor mastication and rapid consumption of feedstuffs, and inadequate water consumption. Clinical signs can vary from anorexia and weight loss to those consistent with severe abdominal pain. In severe cases, spontaneous reflux may occur, with gastric contents visible at the nares. In cases of acute severe abdominal pain, one often makes a diagnosis during exploratory celiotomy. In animals not exhibiting signs of colic warranting surgical intervention, an endoscopic finding of a full stomach after a normally adequate fast (18 to 24 hours) often can confirm the diagnosis. Abdominal radiographs are reserved for smaller horses and ponies. In addition to pain management, specific treatment consists of gastric lavage via nasogastric intubation or massage and injection of fluid to soften the impaction during laparotomy.[98–100]

13.10.2.4 MISCELLANEOUS CAUSES OF GASTRITIS

Nonulcerative gastritis rarely occurs in the horse; however, a single case of emphysematous gastritis caused by *Clostridium perfringens* has been reported.[101]

13.11
13.11—Duodentitis–Proximal Jejunitis (Anterior Enteritis, Proximal Enteritis)

Rebecca S. McConnico

Duodenitis–proximal jejunitis (DPJ) is an inflammatory condition affecting the upper small intestine and resulting in distention, abdominal pain, gastric reflux caused by excessive fluid and electrolyte secretion, and increased peritoneal fluid protein concentration without a significant elevated nucleated cell count. Clinical signs of DPJ 873

874 mimic that of a strangulating or nonstrangulating small intestinal obstruction, so distinguishing between the two syndromes is important because appropriate treatment of small intestinal obstruction usually requires surgical intervention. Studies suggest that the survival rate for horses with DPJ that endured surgical exploratory laparotomy was poor compared with those treated medically, although differences in disease severity may have accounted for the results in these early reports.[1,2] The clinical syndrome of DPJ was well described in the 1980s, and although recognized by its classical presentation, varying degrees of focal intestinal and systemic illness may occur.[1–4] DPJ usually occurs alone but can occur along with gastritis, ileitis, typhlitis, and or colitis.

13.11.1 Pathophysiology

Typical pathologic findings in horses with DPJ include involvement of the duodenum and usually the proximal jejunum.[3] The ileum and large colon usually are determined to be grossly normal. Gastric distention is a common finding and is thought to be caused by hypersecretory mechanisms in the proximal small intestine and a functional ileus of affected enteric segments. The small intestine may be 5 to 7 cm in diameter because of fluid distention with malodorous, red to brown-red intralumenal fluid accumulation. Duodenal (and jejunal) serosal surfaces may have varying degrees and distribution of bright-red to dark-red petechial and ecchymotic hemorrhages and yellow to white streaks. The enteric mucosal surfaces are usually hyperemic and have varying degrees of petechiation and ulceration.

Microscopically, the most severe lesions have been located in the duodenum and proximal jejunum but may extend proximally to the gastric mucosa and aborally to the large intestinal mucosa and submucosa.[3] Microscopic lesions consist of varying degrees of mucosal and submucosal hyperemia and edema. More severe lesions include villus degeneration with necrosis and more severely, sloughing of villous epithelium. The lamina propria, mucosa, and submucosa may have varying degrees of granulocyte infiltration (predominantly neutrophils), and the muscular layers and serosal surfaces contain small hemorrhages. Proximal small intestinal serosal fibrinopurulent exudate is a common finding in the more severe cases; therefore the term *hemorrhagic fibrinonecrotic duodenitis–proximal jejunitis* has been suggested as a more descriptive name for this syndrome.

Horses with DPJ often have evidence of multiple organ involvement such as hepatic changes including congestion and varying degrees of biliary duct hyperplasia. Additional systemic involvement likely is caused by endotoxin absorption, metabolic imbalances such as acidemia, and circulatory changes.

The cause of this syndrome remains an enigma (much like the cause of other inflammatory conditions affecting the intestinal tract). Several microorganisms have been implicated as playing a role in triggering DPJ, including *Clostridium* spp., *Salmonella* spp., and some mycotoxins, but efforts to reproduce the syndrome experimentally have been futile.[5] A recent dietary change with an abrupt increase in dietary concentrate level has been suggested to predispose a horse to developing DPJ because of intraluminal microbial imbalances.

Two intracellular processes control intestinal secretion, the cyclic nucleotide (cyclic adenosine monophosphate and cyclic guanosine monophosphate) and the calcium systems.[6] Agents (inflammatory mediators, microorganisms, toxic agents) can activate adenyl cyclase (vasoactive intestinal peptide, prostaglandin E_2) or guanyl cyclase (bacterial enterotoxins) and induce increases in cyclic adenosine monophosphate and cyclic guanosine monophosphate, respectively. This reaction causes phosphorylation of specific protein kinases, which induce the actual mucosal membrane transport events. Increases in intracellular free calcium may arise from cyclic nucleotide–dependent release of stored calcium within the cell or from increased calcium entry across the cell membrane.[7] Calcium may act through calmodulin, which then can activate membrane-phosphorylating protein kinases. The net effect is increased movement of sodium and chloride into the mucosal cell from the interstitium, with secretion of sodium and chloride into the intestinal lumen. Water follows the directional flux of sodium and chloride through highly permeable intercellular spaces. Several bacterial toxins and endogenous mediators can cause active secretion and contribute to a synergistic mucosal secretory response. Passive secretion of protein-rich fluid into the lumen occurs following damage to the mucosal epithelium, capillary endothelium, and submucosal inflammation in the proximal small intestine. The clinically relevant events that result from active and passive fluid secretion are proximal small intestinal distention and nasogastric reflux, dehydration, and circulatory shock.

The concentration of protein in the peritoneal fluid from horses with DPJ is usually higher than in horses with small intestinal obstruction. A disproportionate increase in total protein concentration relative to nucleated cell count occurs probably by leakage of blood or plasma into the peritoneal cavity without a significant stimulus for leukocyte chemotaxis. Suggested mechanisms for increased abdominal fluid protein concentration include serositis associated with inflamed intestine and small intestinal distention causing passive congestion and increased capillary hydrostatic pressure of visceral peritoneal vessels.[8]

874

Small intestinal ileus is another hallmark sign of DPJ and the pathophysiology is complicated, involving primary and secondary dysfunction of the central, autonomic, and enteric nervous systems and their purported roles in governing intestinal motility.[9] Primary role-players in DPJ-associated ileus include peritoneal inflammation, inflammatory cell migration/activation within the muscularis, small intestinal mechanical distention, and effects of endotoxin absorption. The use of prokinetic agents for treating ileus and gastric/small intestinal distention in horses with DPJ is becoming more common, but veterinarians should realize that a potential restriction on their use is the need for normal intestinal integrity. In spite of that, one may use motility modifiers judiciously. 875

13.11.2 Clinical and Clinicopathologic Signs

The veterinarian has the challenge of differentiating horses with DPJ from horses with small intestinal obstructive lesions so as to avoid surgical intervention (Table 13.11-1). Horses with DPJ typically show signs of acute abdominal pain initially, and then after gastric decompression, volume replacement, and analgesic therapy, the colic signs subside, but signs of lethargy and malaise become more apparent. In contrast, horses with obstructive lesions of the small intestine usually show signs of abdominal pain until the affected viscus is repaired via surgical intervention or the viscus ruptures. Another differentiating characteristic is the large volume (>4 to 20 L with each decompressive effort) of nasogastric reflux that is often malodorous and orange-brown or red-brown. DPJ-affected horses have moderate to severe small intestinal distention palpated on rectal examination, temperature of 38.6° to 39.1° C (101.5° to 102.5° F), dehydration, brick-red mucous membranes, lethargy and absent borborygmi, prolonged capillary refill time, tachycardia (>60 beats/min), and tachypnea. Although the signs of abdominal pain usually resolve after gastric decompression, most horses remain severely lethargic. Without periodic removal of the fluid that accumulates in the proximal intestinal tract, signs of abdominal pain usually recur. Horses with DPJ often require gastric decompression at 2-hour intervals, with 2 to 10 L of fluid recovered each time. Nasogastric tubes left in place for long periods of time cause varying degrees of pharyngitis, laryngitis, and esophagitis.

TABLE 13.11-1 Physical and Laboratory Examination Findings in Horses With Duodenitis–Proximal Jejunitis (DPJ) and an Operable Small Intestinal Lesion

EXAMINATION	DPJ	STRANGULATING OBSTRUCTION	NONSTRANGULATING OBSTRUCTION
Abdominal pain	Acute onset	Acute onset	Acute onset
Attitude	Depressed, painful	Painful	Painful
Heart rate (beats/min)	40–80	≥80	40–80
Respiratory rate (breaths/min)	16–28	24–40	15–35
Rectal temperature (°F)	101.5–102.5	≤101	99–101
Capillary refill time	>3 seconds	≥3 seconds	1.5–3.0 seconds
Intestinal sounds	Mildly to greatly depressed	Greatly depressed to absent	Mildly depressed to absent
Nasogastric reflux	3–4 gallons orange-brown	2–4 gallons, ± malodorous	2–3 gallons with ingesta character, ± malodorous
Rectal examination	Dilated to moderately distended	Moderately to greatly distended	Mild to moderately distended, ± ileal impaction
Response to nasogastric decompression	Depressed, quiet	Temporary to no pain relief	Temporary to no pain relief
Complete blood count	± Increased white blood cells; mature neutrophilia	± Increased white blood cells; slight neutrophilia	Normal to increased white blood cells
Peritoneal fluid protein	>3.0 g/dl and may be >4.5 g/dl	2.5–4.5 g/dl	2.5–3.5 g/dl
Peritoneal fluid nucleated cell count	≤5000/μ l	3000 to >20,000/μl	3000 to 12,000/μl

*Findings in which differences between DPJ and obstructive disorders are often present are italicized.

Typical clinical laboratory findings include an increased packed cell volume and total plasma protein reflective of volume depletion, a metabolic acidosis (with elevated anion gap) in longstanding or severe cases, an increased peritoneal fluid protein concentration (often >3.5 g/dl), and a mild to moderate elevation of the peritoneal white 875
blood cell count, although the count usually is less than 10,000 cells per microliter.[3,4] The peritoneal fluid is 876
usually yellow and turbid, but in severe cases diapedesis occurs resulting in a serosanguinous color. The white blood cell count in the peripheral blood may be normal, decreased, or increased. In addition, hyponatremia, hypochloremia, hypokalemia, and acid-base alterations (elevated anion gap) are often evident. The loss of enteric bicarbonate through evacuation of enterogastric reflux and poor tissue perfusion from hypovolemia can lead to metabolic acidosis. One makes a definitive diagnosis of DPJ in most cases by gross examination of the duodenum and proximal jejunum at surgery or at necropsy. Some equine practitioners have observed an apparent

geographic relationship in the incidence and severity of the syndrome, with more cases occurring in the southeastern United States.

13.11.3 Treatment

Horses with DPJ appear to share a common characteristic clinical presentation, and the mechanisms leading to electrolyte imbalances, fluid loss, ileus, and endotoxemia and septicemia are similar. Treatment regimens are supportive and aim at plasma volume replacement (usually in the form of crystalloid fluid replacement), analgesia and antiinflammatory therapy, gastric decompression, antiendotoxin therapy, antimicrobial therapy if indicated, nutritional support, and nursing care.

13.11.3.1 FLUID THERAPY

One should institute aggressive intravenous polyionic fluid therapy immediately in a horse with DPJ. One should calculate the total fluid deficit based on clinical assessment of dehydration (e.g., for 8% or moderate dehydration, 0.08 × 450 kg body mass = 36 L) and should administer replacement fluids rapidly (up to 6 to 10 L per hour per 450-kg adult horse). Administering intravenous hypertonic saline (7%) may be useful to treat hypovolemic shock in horses with severe circulatory shock. The use of 1 to 2 L of hypertonic saline (7% NaCl) improved systemic blood pressure and cardiac output in horses with hemorrhagic shock and in a model of equine endotoxemia.[10] If one chooses this treatment option, intravenous administration of replacement isotonic fluids must follow immediately to maintain tissue integrity. One should not allow horses with significant volumes of gastric reflux to ingest foodstuffs or liquids orally.

Once one has administered replacement fluids and the horse is well hydrated, one should administer maintenance fluid amounts, which may be as high as 120 ml/kg/day. Unfortunately, the intravenous fluid therapy itself may accelerate the flux of fluid from the vasculature into the intestinal lumen because of a reduction in intravascular oncotic pressure and an increased capillary perfusion pressure, which can result in an increased volume of gastrointestinal reflux. However, the veterinarian should not consider reducing the volume of intravenous fluid therapy because excessive fluid losses continue to occur. One should monitor plasma protein concentration, overall hydration, and the volume of reflux and then determine the rate of intravenous fluid administration. During the initial hours of therapy, even aggressive intravenous fluid administration results in only moderate clinical improvement. The clinical response, as evidenced by improved hydration status, decreased nasogastric reflux, improved attitude, and improvement in values reflecting kidney function (decreased blood urea nitrogen and creatinine), correlates with improvement of intestinal damage.

13.11.3.2 HYPOPROTEINEMIA

Horses with DPJ that continue to reflux large volumes of enterogastric fluid frequently for more than 36 to 48 hours most likely will experience protein loss from the inflamed and disrupted intestinal mucosal barrier and from systemic protein catabolism. Decreased colloid oncotic pressure leads to decreased effective circulating fluid volume and edema. Total plasma protein may decline to below 4 g/dl and the albumin may decrease to below 2.0 g/dl. Fresh or thawed frozen plasma is ideal for replacement of functional proteins. One should consider treatment with intravenous plasma therapy or a combination of plasma and synthetic colloid (e.g., synthetic amylopectin) as soon as one sees evidence of a consistent decline in total plasma protein or albumin (<2.0 g/dl) or if the horse is developing dependent edema. Fresh plasma (preferred) or fresh frozen plasma is the treatment of choice if coagulation disorders accompany protein loss. An average-size horse (450 kg)

requires 6 to 10 L of plasma (albumin 3.0 g/dl) or synthetic colloid to improve plasma oncotic pressure. Administration of additional aliquots of 2 to 10 L of a balanced colloidal solution may be necessary if the DPJ crisis continues. In addition to albumin (the major colloid component), plasma contains other components that provide overall systemic support (e.g., fibronectins, complement inhibitors, elastase and proteinase inhibitors, antithrombin III). One may administer a 6% solution of hydroxyethyl starch (Hetastarch (6%), Abbott Laboratories, North Chicago, Illinois), a synthetic colloid, at 5 to 10 ml/kg. Because of the large size of the starch molecules, this solution is an effective plasma volume expander, resulting in sustained dose-dependent decreases in packed cell volume and plasma protein concentration with increased oncotic pressure. The cost of an appropriate amount of commercial plasma or synthetic colloid solution for treatment of adult horses with DPJ may be prohibitive but can be life-saving. 876

877

13.11.3.3 ANTIENDOTOXIN THERAPY

Horses with enteritis frequently absorb large amounts of endotoxin from the disrupted intestinal mucosal barrier, therefore putting these horses at a high risk for laminitis. One should monitor digital pulses every 4 to 6 hours until systemic signs of enteritis have abated (fever, leukopenia, etc.). Treatment to combat endotoxemia is critical, and several therapeutic approaches are available. Choice of treatment options is based on severity of disease, renal function, hydration status, and economics. The reader is referred to Chapter 13.7 for a thorough discussion of endotoxemia pathophysiology, treatment, and prevention.

13.11.3.4 ANTIINFLAMMATORIES AND ANALGESIA

Nonsteroidal antiinflammatory drugs are the most frequently used group of drugs for treatment of abdominal pain in horses (flunixin meglumine 1.1 mg/kg intravenously every 12 hours or phenylbutazone 2.2 mg/kg orally or intravenously every 12 hours). The clinician must weigh the benefit of the analgesic effect of nonsteroidal antiinflammatory drugs with the possibility of further damage to the intestine by potentially blocking the protective effects of intestinal mucosal prostaglandins.

One should consider other classes of drugs for treating colic associated with DPJ. Butorphanol (Torbugesic; an opioid analgesic) at 0.06 to 0.1 mg/kg with detomidine (Dormosedan; an α-agonist) at 0.01 to 0.02 mg/kg given intramuscularly every 6 to 8 hours is a useful combination that has minimal effects on gastrointestinal motility.

13.11.3.5 ANTIMICROBIAL THERAPY

Because *Clostridium* spp. are suspected as a causative agent of DPJ, penicillin often is administered to affected horses. However, one should consider broad-spectrum antimicrobial coverage for horses with DPJ. One can add an aminoglycoside (gentamicin, amikacin) or third-generation cephalosporin (ceftiofur [Naxcel], Upjohn Co., Kalamazoo, Michigan) to the penicillin therapy, keeping in mind the potential adverse effects of these drugs on renal function.

13.11.3.6 ANTISECRETORY THERAPY

Effective antisecretory medications targeting the equine small intestine have not been identified.

13.11.3.7 MANAGEMENT OF NUTRITION

One should consider the nutritional needs of horses with DPJ. Most horses have a total body protein loss from cachexia and a protein-losing enteropathy. Total parenteral nutrition may be indicated in horses that remain anorectic for more than 3 to 4 days. Parenterally administered solutions containing glucose, balanced amino acid solutions, lipid emulsions, balanced electrolyte and trace minerals, and vitamins have been administered to adult horses with small intestinal ileus or enterocolitis. Based on a small number of horses, this therapy has proved promising in terms of minimizing protein losses and decreasing the duration of illness. Providing for part of the nutritional requirements of the horse (8000 to 12,000 kcal/day) is possible with glucose–amino acid solutions, which are of moderate cost. One may suppose reasonably that providing nutritional support to an anorectic, severely ill horse will facilitate the healing process and even shorten the duration of illness. Thus the overall cost of providing parenteral nutritional supplementation to horses with DPJ may well be offset by quicker recovery and diminished requirements for other, expensive treatments.

13.11.3.8 INTESTINAL MOTILITY MODIFIERS

Normal (healthy) intestine is necessary for optimum performance of prokinetic agents in horses. Many motility-modifying agents likely are ineffective in cases of DPJ. However, some benefit may come of the judicious use of prokinetic agents in inflammatory conditions of the equine intestine, particularly if the agent provides additional effects such as analgesia. For example, lidocaine infusion has several actions that may be beneficial in the treatment of ileus, including suppression of primary afferent firing, antiinflammatory properties, an observed analgesic effect, and direct stimulation of smooth muscle.[9] An infusion dose of 15 to 20 mg/min over 5 to 6 hours has been recommended. The reader is referred to Chapters 13.6 and 13.15 for a complete description of motility modifying agents.

13.11.3.9 NONRESPONSIVE CASES

Medical therapy is sufficient in most cases of DPJ, but in those cases in which the horse continues to produce copious enterogastric reflux, one may consider surgery as an option. Refractory cases have been observed to improv e with surgical intervention; however, some horses with refractory DPJ have been observed to recover with supportive medical care alone even after 20 days of refluxing large amounts of fluid every 2 to 4 hours (personal observation). The decision of when to intervene surgically often is difficult. One may elect surgery to determine the extent of gross pathologic condition and intestinal distention and to perform intestinal bypass so as to direct enterogastric reflux toward the cecum and colon, where the fluid can be reabsorbed. Allen and Clark[5] have described two approaches for surgical therapy in such cases. A standing right flank laparotomy with resection of the last rib has been used to approach the duodenum and cecal base. Using this approach, one 877
makes a small stoma between the duodenum and cecum using a handsewn 1.0- to 1.5-cm side-to-side 878
anastomosis. The stoma may act as a shunt to decompress the proximal small intestine and deliver the small intestinal fluid to the cecum for reabsorption. Following recovery, the stoma likely will close.

When a veterinarian is confronted with a horse exhibiting abdominal discomfort, with small intestinal distention palpable per rectum, and greater than 2 L of gastric reflux, the veterinarian should recommend referral of the horse to a facility capable of performing abdominal surgery. The chance that such a horse has an intestinal obstruction is too great to decide to treat it as if it may have DPJ. Surgery on such horses is not unusual, even though DPJ is possible, to rule out an obstruction. At present, the survival of horses with DPJ that undergo surgery is much greater than previously described, and certainly greater than that of horses with

small intestinal obstruction that do not have surgery. Horses with DPJ that receive appropriate therapy have a reasonably good chance of making a full recovery. Horses that continue to have frequent episodes of voluminous nasogastric reflux and systemic signs of endotoxemia and septicemia have a poorer prognosis for recovery. Frequent complications of DPJ include laminitis, thrombophlebitis, and weight loss.

13.12 13.12—Proliferative and Inflammatory Intestinal Diseases Associated With Malabsorption and Maldigestion

Malcolm C. Roberts

Malabsorption is associated with pathologic conditions of the small intestine characterized by substantial reduction of the available absorptive surface area. By virtue of the extent of the morphologic changes, interference with digestive processes occurs, although maldigestion may be difficult to confirm in the absence of assessment measures. The small bowel problem may alter the composition and availability of substrate presented for fermentation in the large intestine. Clinical signs may be modified or accentuated if involvement of the large intestine is concomitant. Diarrhea indicates significant alterations in bidirectional fluid and electrolyte fluxes and in large intestinal transit.

The clinical signs of chronic wasting and poor body condition, although nonspecific for a diagnosis of malabsorption antemortem, can be attributed to proliferative or inflammatory intestinal disorders, often collectively

referred to as chronic inflammatory bowel diseases.[1] Clinical signs include alimentary lymphosarcoma, granulomatous enteritis, multisystemic eosinophilic epitheliotropic disease (MEED), and lymphocytic-plasmacytic enterocolitis—conditions affecting young and adult horses. Proliferative enterocolitis,[2] a transmissible disease of foals 3 to 7 months of age characterized by significant small intestinal pathologic changes, will be included in this group. However, several other primarily small intestinal conditions described from a morphologic perspective, such as chronic postinfarctive inflammation and mycobacterial infections,[3] will not be discussed. In addition, a single case of AA amyloid-associated gastroenteropathy in an 18- year-old Morgan stallion that had evidence of severe malabsorption based on poor d-xylose absorption is included.[4]

For comparative purposes, Table 13.12-1 lists the clinical and clinicopathologic features of the diseases, and Tables 13.12-2 and 13.12-3 present the gross morphologic and histopathologic findings, respectively. The extent of small 878
intestinal disease is the key to determine whether one can demonstrate malabsorption based on abnormal 881
carbohydrate absorption. As described in Chapter 13.4, this is not an all-or-nothing situation. In the same animal the staging of the pathologic changes differs in different regions of the small and large intestines, thus influencing severity of clinical signs and absorption findings. Furthermore, the extent of pathologic changes in different animals with ultimately the same morphologic diagnosis affects absorption studies and progress of the disease. Early diagnosis remains a challenge, and even multiple intestinal biopsies taken at exploratory laparotomy may prove unhelpful. By contrast, intestinal infiltration with the predominant cell types can be found in grossly normal appearing intestinal tissue.

TABLE 13.12-1 Predominant Clinical and Clinicopathologic Features of Horses With a Primary Problem of Chronic Wasting (or a More Rapid Weight Loss) Attributable to Proliferative and Inflammatory Bowel Diseases

CONDITION	AGE RANGE/ BREED	OTHER PRESENTING SIGNS	DERMATITIS/CORONITIS	HEMATOLOGY	CHEMISTRY*	ABSORPTION TESTS
Alimentary lymphosarcoma	2 to aged Majority ≤4 years None*	Poor appetite, edema, depression, occasional fever, occasional diarrhea or colic, pain	+/+/− Scurfy skin	Anemia, neutrophilia; lymphocytosis is rare	Decreased albumin Total protein normal to increased Increased globulin	Reduced absorption; partial to complete malabsorption
Granulomatous enteritis	1–6 years Majority ≤3 years Standardbred	Severe wasting, edema, poor to ravenous appetite, depression, infrequent diarrhea, occasional slight fever	+/− Scurfy skin; severe lesions rare	Anemia Leucocytes normal to slightly decreased or increased	Decreased albumin Total protein normal to decreased GGT normal ALP normal to increased	Reduced absorption; partial to complete malabsorption
Multisystemic eosinophilic epitheliotropic disease	1–17+ years Majority ≤4 years Standardbred, Thoroughbred	Severe wasting, edema, appetite poor to often ravenous, slight fever, diarrhea or soft feces common; depression, colic rare, oral ulcers	++++/Severe skin lesions and ulcerative coronitis prominent	Anemia rare to slight; neutrophilia and eosinophilia rare	Decreased albumin Total protein normal to decreased GGT normal to increased ALP normal to increased	Slower absorption; reduced or normal peak concentration delayed (shifted to right)
Lymphocytic-plasmacytic enterocolitis	3–26 years None	Inappetance, depression diarrhea, colic, edema	—	Normal	Decreased albumin Decreased total protein Increased fibrinogen	Inadequate absorption or delayed peak

Proliferative enteropathy	3–7 months Arabian	Depression, colic, diarrhea, edema, appetite often normal, concurrent infection	+/– Scurfy skin	Anemia Leukocytosis	Decreased albumin Decreased total protein Increased CPK	Normal absorption in 3 of 3 foals tested

* *GGT,* γ-Glutamyltransferase; *ALP,* alkaline phosphatase; *CPK,* creatine phosphokinase; *none,* no predominant breed.

TABLE 13.12-2 Gross Morphologic Features of Proliferative and Inflammatory Bowel Diseases of Horses

CONDITION	SMALL INTESTINE	LARGE INTESTINE	OTHER ORGANS/ SYSTEMS
Alimentary lymphosarcoma	**Constant;** extensive thickening, thickened mucosa, fissures, serosal plaques, nodules, congestion	**Infrequent;** unremarkable to thickened segments	Mesenteric lymph nodes (MLNs) massively enlarged Other lymph nodes involved in liver, spleen, stomach (rare)
Granulomatous enteritis	**Constant;** thickened wall, thickened mucosa, fissures, widespread ulceration (tiny ulcers)	**Common;** generally discrete	MLNs enlarged, edematous Stomach commonly affected (generally discrete) Liver, pancreas rare
Multisystemic eosinophilic epitheliotropic disease	**Common;** diffusely thickened, especially proximal duodenum and distal ileum; serosal nodules or granularity; ulceration	**Constant;** severe; segmental, or multifocal granulomata; mucosal (predominantly) and transmural thickening; extensive ulcers	MLNs (and other nodes) enlarged Stomach and esophagus commonly affected Liver/pancreas commonly affected; may be hyperkeratotic Skin: exudative dermatitis, ulcerative coronitis
Lymphocytic-plasmacytic enterocolitis	**Constant;** mucosal/ submucosal edema, prominent folds	**Common;** edema, congestion, areas of mucosal ulceration	MLNs enlarged
Proliferative enteropathy	**Constant;** significant mucosal thickening, corrugated appearance from proximal jejunum to distal ileum	**Uncommon;** submucosal edema	MLNs unremarkable

TABLE 13.12-3 Significant Histopathologic Features of Proliferative and Inflammatory Diseases of Horses

CONDITION	SMALL INTESTINE	LARGE INTESTINE	OTHER ORGANS/ SYSTEMS
Alimentary lymphosarcoma	Villous atrophy (partial to total); crypts disappear with hyperplasia; infiltrate of pleomorphic lymphoid cells, plasma cells; transmural	Nothing evident to diffuse mucosal infiltration	Mesenteric lymph nodes (MLNs): extensive infiltration; more moderate in other lymph nodes (hepatic, abdominal, inguinal, superficial)
Granulomatous enteritis	Villous atrophy (partial to total), crypt hyperplasia and abscesses, diffuse granulomatous inflammation; mononuclear cells (lymphoid), giant cells, epithelioid foci; lymphangiectasia	Similar infiltrate usually discrete; mucosa, submucosa	Similar infiltrate; stomach discrete MLNs: discrete to florid macrophage infiltration Diffuse cortical hyperplasia
Multisystemic eosinophilic epitheliotropic disease	Villous atrophy rare; lymphocytic and eosinophilic infiltration most severe in cranial duodenum, ileum, ileocecal junction; infiltrate more widespread than gross lesions	Segmental/multifocal lesions, severe infiltration, reactive fibrosis, tissue eosinophilia, walled off granulomata, central necrotic core of eosinophilic material	Similar infiltration with fibrosis of MLNs, liver, pancreas Skin: acanthosis, hyperkeratosis, diffuse infiltrate of eosinophils; lymphocytes in dermis; focal eosinophilic accumulations
Lymphocytic-plasmacytic enterocolitis	Villous blunting to atrophy; moderate to severe infiltration of lymphocytes, plasma cells; edema, dilated lymphatics	Similar infiltrate, less remarkable	Minimal evidence
Proliferative enteropathy	Villous shortening, severe hyperplasia of crypt epithelium, small curved bacteria in apical cytoplasm, mononuclear infiltrate	No evidence	No evidence

13.12.1 Alimentary Lymphosarcoma

Alimentary lymphosarcoma of the horse may represent a primary neoplasia of the gut associated lymphoid tissue with significant cellular infiltration of the small intestine and associated lymph nodes with minimal large

intestinal or systemic involvement. Case series and pathology reports indicate that young horses 2 to 4 years of age primarily are affected, although the age range can be broad.[5–7] No breed or sex predilection exists. Prevalence is unknown. Despite the progressive nature of lymphomata, onset of clinical signs can be rapid and the animal may become acutely ill. As with all adult cases of chronic inflammatory bowel disease, antemortem diagnosis is by a process of exclusion and usually is confirmed post mortem. Frequently, the horse has anemia, thrombocytopenia, neutrophilia or neutropenia, hypoalbuminemia, normal serum protein or hyperproteinemia, and hypergammaglobulinemia. Lymphocytosis is rare. One may palpate intraabdominal masses, mainly enlarged mesenteric lymph nodes, rectally. Abdominocentesis has been of diagnostic value. Carbohydrate absorption tests usually reveal partial to total malabsorption indicative of the severely reduced surface area resulting from significant villous atrophy and the extensive mucosal or transmural infiltration. Rectal biopsy has aided diagnosis. Early confirmation of a suspected diagnosis necessitates exploratory laparotomy to obtain multiple intestinal and lymph node biopsies. In the future, markers of cancer cells may become available and may be cost-effective to aid diagnosis. Prognosis is poor. Natural progress of the disease is unknown. Most horses are presented in an advanced state of disease. Immunosuppressive drugs or chemotherapy may afford temporary improvement. However, outcome is unaffected.

13.12.2 Granulomatous Enteritis

The chronic wasting condition granulomatous enteritis was first described in 1974[8]; 9 of 10 horses were young Standardbreds. Most affected horses are 2 to 3 years of age. Case reports from many countries revealed a predominance of Standardbred over Thoroughbred horses by three to one.[9,10] Some of the Standardbreds were related, implicating a genetic predisposition. Prevalence is low. The condition is sporadic and has an insidious onset, and the course can be protracted. Significant diagnostic features include anemia, slight increases or decreases in white blood cell counts, hypoalbuminemia, normal serum protein or hypoproteinemia, occasional increases in serum alkaline phosphatase activity, normal serum γ-glutamyltransferase activity, and enlarged mesenteric lymph nodes on rectal palpation. Reduced carbohydrate absorption to the level of partial to total malabsorption is reported frequently, consistent with the severe morphologic changes throughout the small intestine. One can attribute the low proportion of horses exhibiting diarrhea[9,10] to the preferential distribution of inflammatory infiltration in the small intestine,[11] with lesser involvement of the large intestine. Rectal biopsy can be a useful aid to diagnosis.[12]

Treatment of horses with granulomatous enteritis with a variety of drugs, particularly corticosteroids, has not affected the outcome except in the short term.[13] One successful response has been reported. Prolonged corticosteroid administration produced clinical remission in a 6-year-old Standardbred gelding based on improvement in clinical signs and in d-xylose absorption.[14] Five months after cessation of approximately 5 months therapy, d-xylose absorption was normal and the horse was bright, alert, and resumed a level of athletic performance. Parenteral administration of dexamethasone sodium phosphate was tapered to achieve a minimal effective dose to reduce intestinal inflammation and abolish clinical signs. Adverse effects were not reported. The outcome of this single case is encouraging. Surgery may be indicated if the disease is localized. Two young horses underwent resection of the thickened terminal small intestine to confirm a diagnosis and provide a means of treatment; one horse died 4 months after surgery, and the other has remained clinically normal for at least 10 years.[10]

The cause of granulomatous enteritis is unknown. Several infectious agents have been implicated, including *Mycobacterium avium*.[15] The condition may represent a granulomatous hypersensitivity reaction. Immune-mediated responses to dietary, parasitic, or bacterial antigens may be important initiating factors.[1] Recently, six

cases purported to represent granulomatous enteritis were linked to environmental contamination with aluminum.[16] Although the case definition was flawed and problems existed with the data and interpretation,[17] the report nevertheless raised the possibility that a toxicologic basis may exist for some equine inflammatory bowel disorders.

881

882

13.12.3 Multisystemic Eosinophilic Epitheliotropic Disease

MEED encompasses disorders characterized by a predominant eosinophilic infiltrate in the gastrointestinal tract, associated lymph nodes, liver, pancreas, skin, and other structures and accompanied by some degree of malabsorption and enteric protein loss. The disorders include chronic eosinophilic gastroenteritis,[18] eosinophilic granulomatosis,[9] chronic eosinophilic dermatitis,[19] and probably basophilic enterocolitis.[20] The condition differs from idiopathic eosinophilic enterocolitis,[10] in which segmental lesions in the small or large intestine induce signs of colic requiring surgical intervention[21,22] without evidence of malabsorption or multisystem involvement.

Although prevalence is low, MEED appears to be more common than granulomatous enteritis based on the accumulated published reports and personal experience in Australia and the United States. Most affected horses are 2 to 4 years of age, and Standardbreds and Thoroughbred are reported to predominate. The condition is sporadic and has an insidious onset, and the course is protracted with a duration of 1 to 10 months. Diarrhea is common in contrast to granulomatous enteritis. Severe skin lesions with exudative dermatitis and ulcerative coronitis are prominent and frequently are the principal reason for veterinary attention being sought. Despite extensive tissue eosinophilia, systemic eosinophilia is rare. Hematologic values are usually unremarkable. Notable features include hypoalbuminemia and normal serum protein or hypoproteinemia, and because of liver involvement, serum γ-glutamyltransferase and alkaline phosphatase activities may be increased. Most reports of carbohydrate absorption test findings (glucose or d-xylose) indicate retarded absorption and a reduced or normal peak concentration delayed to at least 180 minutes. One can interpret this pattern as the existence of sufficient small intestinal absorptive capacity to enable moderate absorption with possibly delayed gastric emptying or ileocecal ejection. Morphologic changes are less pronounced in the small intestine than in the large intestine,[9] and small intestinal lesions predominate segmentally in the proximal duodenum and distal ileum. Furthermore, significant hyperkeratosis of the fundic region may contribute to gastric muscle contractile disruption. Diarrhea can be a consequence of the severe segmental or multifocal granulomatous lesions in the large intestine with mucosal and transmural thickening and extensive ulceration. Abundant fibrosis is a feature of all affected tissues (see Table 13.12-3).

The cause of MEED is unknown and could represent a chronic ongoing immediate hypersensitivity reaction against undefined antigens ingested or excreted into the lumen from parasitic, bacterial, or dietary sources. Infectious agents have not been identified.[18,19] Widespread use of the avermectins has tended to reduce parasite loads and composition to favor small strongyles (cyathostomes). Eosinophilia is a feature of parasitism in the equine intestinal tract, although nematodes rarely have been identified in any lesions of MEED.[3,18] However, failure to detect larval structures in these lesions may be attributable to chronicity of the disease and destruction of the parasites in tissue.[10]

Biopsies of the rectal mucosa[12] or of the skin, liver, intestinal tract, and lymph nodes may assist in diagnosis. Treatment has been attempted with a variety of drugs, including antibiotics, corticosteroids, and anthelmintics with larvicidal activity. Immediate improvement has not been borne out in the long term. Prognosis is poor. The clinical objective is to reach a tentative diagnosis early in the course of the disease for intervention to be more

than transient. Unlike the other conditions (see Table 13.12-1), MEED has definitive liver and pancreatic involvement, and thus maldigestion may make a significant contribution to the wasting disease. For example, the lowered albumin and protein could result in part from impaired pancreatic enzyme digestion, and the effects of inflammatory lesions in the liver and ileum may decrease bile salt concentrations.

13.12.4 Lymphocytic-Plasmacytic Enterocolitis

The morphologic findings in lymphocytic-plasmacytic enterocolitis reflect the predominant infiltrative cellular elements of this rarely encountered condition. A retrospective study of 14 horses[23] provided the information presented in the tables. No specific clinical or clinicopathologic features differentiate this condition antemortem from other inflammatory diseases of adult horses. Carbohydrate absorption was abnormal or delayed in 9 of 12 horses, consistent with the predominance of small intestinal pathologic changes. Rectal biopsies were abnormal in 3 of 7 horses, two of which were reported as having lymphocytic-plasmacytic proctitis. Prognosis is poor. Treatment has been unsuccessful, probably because of the advanced nature of the condition at the beginning of treatment.

13.12.5 Proliferative Enteropathy

Proliferative enteropathy has not been associated with abnormal carbohydrate absorption based on three horses subjected to carbohydrate absorption tests. However, the florid mucosal lesions in the jejunum and ileum undoubtedly contribute to impaired digestive function and potential malabsorption of vitamins, minerals, and 882
amino acids in the distal small intestine. The condition affects foals 3 to 7 months of age, particularly those that 883
have been weaned recently. The disease is caused by *Lawsonia intracellulare,* an obligate intracellular bacterium found in the cytoplasm of proliferative crypt epithelial cells of the intestine. The condition in a foal was described first as intestinal adenomatosis,[24] because of similarity to the swine disorder of the same name. Later, molecular studies showed that intestines from an affected foal contained *L. intracellulare* sequences as determined by polymerase chain reaction analysis and confirmed by Southern blot hybridization.[25] Recently, studies of a cluster of affected foals on three breeding farms in Canada provided much information on the clinical syndrome, laboratory investigations, and response to treatment.[2]

Two of the three farms bred Arabians, hence a demographic predominance of Arabian foals exists. Clinical signs included depression, rapid and significant weight loss, edema, diarrhea, and colic. Poor body condition, a rough hair coat, and potbelly appearance were common findings. Other problems often were concurrent, including respiratory tract infection, dermatitis, intestinal parasitism, and gastric ulceration. Significant laboratory findings were anemia, transient leucocytosis, hypoalbuminemia, hypoproteinemia, and elevated serum creatine kinase concentrations.

Diagnosis was confirmed by identifying characteristic intracellular bacteria within the apical cytoplasm of proliferating crypt epithelial cells using silver stains and by results of polymerase chain reaction analysis and immunohistochemical testing. Antemortem diagnosis relied on clinical signs, hypoproteinemia, and exclusion of common enteric infections. One can confirm diagnosis in live animals by fecal polymerase chain reaction analysis (positive in 6 of 18 foals tested) and serologic testing; 7 foals with proliferative enteropathy were evaluated serologically and had antibodies against *Lawsonia intracellulare*.[2]

Treatment is effective. Most foals received erythromycin estolate (15 to 25 mg/kg per os every 6 to 8 hours), alone or with rifampin (7 to 10 mg/kg per os every 12 hours) for 2 to 4 weeks. Foals frequently needed

supportive therapy at the outset for stabilization. Response to therapy has been excellent.[2] Rapid improvement in clinical signs even within 24 hours preceded the rise in plasma protein concentration. The source of the infection was undetermined. No apparent link existed between the three farms and a swine operation or solid and liquid waste disposal on pasture. However, one cannot exclude airborne spread of dried fecal material over distances. Comparisons of epidemiologic findings from the swine disease indicated that overcrowding, feed changes, antibiotic usage, and mixing and transportation were potential risk factors at two of the farms. Recent weaning appeared to be a key element in the pathogenesis.

13.13 13.13—Inflammatory Diseases of the Gastrointestinal Tract Causing Diarrhea

Samuel L. Jones

13.13.1 Equine Acute Diarrhea

Acute diarrhea caused by colitis in adult or young horses is a potentially life-threatening disorder of a variety of causes (Table 13.13-1) characterized by hypersecretion of fluid, motility disturbances, altered microbial flora in the colon, and an impaired mucosal barrier caused by direct injury or inflammation. Many of the clinical and clinicopathologic features are similar regardless of the cause. Severe dehydration with profound electrolyte abnormalities is common, as is systemic inflammation from absorption of endotoxin or other bacterial products through the compromised mucosa. Gastrointestinal protein loss may result in reduced colloid oncotic pressure from hypoproteinemia, leading to tissue edema. Colitis is a highly catabolic disorder, and weight loss may be rapid and severe. Some cases of colitis may be complicated by extensive mucosal ulceration, serosal inflammation, or mural ischemia/infarction extending from the inflammation or resulting from coagulopathies. Thus diagnostic measures aimed at determining the cause necessarily must be accompanied by clinical and laboratory assessment of hydration, electrolyte and acid-base balance, plasma protein concentration and colloid oncotic pressure, organ function, and evaluation of the degree of systemic inflammation and of the integrity of the intestinal wall. Although therapeutic strategies are similar for many causes of colitis, consisting primarily of control of local and systemic inflammation, maintenance of fluid and electrolyte balance, promotion of tissue perfusion, replacement of plasma protein, preservation of colloid oncotic pressure, promotion of mucosal repair, restoration of the microbial ecology of the colon, and nutritional management, some causes of acute colitis have specific therapies aimed at eliminating the cause.

13.13.2 Infectious Diseases

A variety of infectious organisms has been identified as causes of acute colitis in adult horses. The clinical syndromes associated with these infections are indistinguishable in most horses. However, appropriate diagnostic tests including fecal bacterial culture, fecal bacterial toxin analysis, PCR, and/or serology may identify specific infectious organisms.

13.13.2.1 SALMONELLOSIS

13.13.2.1.1 Pathogenesis

Salmonella is a genus of gram-negative facultatively anaerobic bacteria that are common gastrointestinal pathogens in horses. Many serotypes of *Salmonella* have been reported to infect horses, but those classified in group B appear to be associated more commonly with disease than those in other groups. Group B includes *S. typhimurium* and *S. agona,* two of the species most frequently isolated from horses.[1–3] *S. typhimurium* is the most pathogenic serotype in horses and is associated with a higher case fatality rate than other species of *Salmonella*.[1] The number of horses that are infected inapparently with and actively shed *Salmonella* in their feces has been reported to be as high as 10% to 20%, but actual prevalence of *Salmonella*-shedding in the general horse population is likely to be much lower, less than 1% to 2%.[4] Horses shedding salmonellae are a potential source of infection to susceptible horses,[1,5] as are environmental reservoirs.[6–8] For these reasons, salmonellosis is one of the most common nosocomial diseases in horses. Nosocomial salmonellosis significantly affects morbidity and mortality in hospitalized horses.[9] The emergence of multidrug resistance in equine *Salmonella* isolates has been a cause of concern because of the importance of salmonellosis as a nosocomial disease and because *Salmonella* represents a significant zoonotic pathogen.[7,10–12]

The virulence of the bacteria varies tremendously with serotype and even among strains of the same serotype in part because of the important role of host susceptibility in the pathogenicity of particular organisms. The infective dose is generally millions of organisms inoculated orally, but various 884
environmental and host factors can reduce the infective dose to a few thousand or even hundreds of 885
organisms.[13–15] Environmental factors or stresses that increase susceptibility to *Salmonella* infection are not well defined, but high ambient temperature, for example, is known to increase the prevalence of salmonellosis in horses greatly. Indeed, the peak incidence of salmonellosis in horses occurs in late summer and fall.[6,14,15] Other environmental and host factors that increase the risk of *Salmonella* infection include transportation, antibiotic administration, gastrointestinal surgery, general anesthesia, preexisting gastrointestinal disease, change in diet, and immunosuppression.[1,8,15]

TABLE 13.13-1 Differentials and Diagnosis of Some Causes of Acute Diarrhea in Adult Horses

CATEGORY	DIFFERENTIALS	DIAGNOSIS
Infectious	Salmonellosis	Fecal culture (five consecutive)
		Fecal polymerase chain reaction (PCR)
	Clostridium perfringens	Quantitative fecal culture
		Fecal toxin immunoassay or PCR
	Clostridium difficile	Fecal culture
		Fecal toxin immunoassay or PCR
	Lawsonia intracellulare	Serologic testing
		Fecal PCR
		Small intestinal ultrasound
	Ehrlichia risticii	Fecal or blood PCR
		Serologic testing
Parasitic	Strongylosis	Fecal egg counts
		Cranial mesenteric artery palpation
		Serum immunoglobulin G(T)
	Cyathostomiasis	Fecal egg count
		Rectal biopsy
		Cecal or colonic biopsy
Toxic	Nonsteroidal antiinflammatory drugs	History and clinical signs
		Right dorsal colon ultrasonography
		Laparoscopy or laparotomy
	Cantharidin	History of exposure
		Fecal or urine cantharidin concentrations
	Arsenic	History of exposure
		Fecal, blood, urine, or tissue arsenic concentrations

Miscellaneous	Carbohydrate overload	History of inappropriate ingestion of carbohydrates
		Blood lactate concentration
	Sand enteropathy	Auscultation of ventral colon
		Fecal sand content
		Abdominal radiography

Host factors that restrict gastrointestinal colonization and invasion by pathogens include gastric pH, commensal gastrointestinal flora, gastrointestinal motility, the mucosal barrier and mucosal immunity.[1,16] Gastric acidity is an important defense mechanism preventing live organisms from reaching the intestine. Altering the gastric pH with histamine$_2$ receptor antagonists, for example, may increase susceptibility to infection. Gastrointestinal flora inhibits the proliferation and colonization of *Salmonella* by secreting bacteriocins, short-chain fatty acids, and other substances that are toxic to *Salmonella*. In addition, elements of the normal flora compete for nutrients and space, especially on the mucosa.[16] Being predominantly anaerobic, the normal flora maintain a low oxidation-reduction potential in the environment of the large intestine, which inhibits the growth of many bacterial pathogens.[17] The importance of normal host gastrointestinal ecology is illustrated by the fact that disturbances of the colonic flora with antibiotics, changes in feed, ileus, or other underlying gastrointestinal disease greatly increase the susceptibility of the host to infection by *Salmonella,* often resulting in serious disease.

The immune status of the host may be one of the most important factors determining not only the susceptibility to *Salmonella* infections but also the degree of invasion and subsequent outcome of the infection. Local immunity, such as mucosal antibody secretion and enterocyte-derived cationic peptides, prevents colonization of the mucosa.[16,18,19] Opsonizing antibodies and activation of the complement cascade are important in fighting systemic invasion by *Salmonella* by increasing the efficiency of phagocytosis and by direct bactericidal activity. Humoral immunity, however, is often ineffective in 885
preventing disease and dissemination once invasion occurs and *Salmonella* has established in its 886
intracellular niche. Following invasion, *Salmonella* is capable of surviving and multiplying within macrophages, rendering humoral (noncellular) immune systems ineffective.[20,21] Specific cellular immunity may be the most effective defense mechanism in the host arsenal against dissemination and systemic infection by *Salmonella*.[21,22] Oral inoculation with small numbers of virulent organisms may induce protective immunity in horses and calves, but the duration of the immunity is not known.[23,24] Oral and parenteral vaccines using killed or attenuated organisms and bacterial products have been promising but are effective only against homologous organisms and are usually not cross-protective among different serogroups.[23–25]

In adult horses, *Salmonella* primarily infects the cecum and proximal colon, causing enterocolitis, and the ability to disseminate beyond the intestine and cause enteric fever is limited. In foals, however, salmonellosis often is associated with septicemia. The ability of *Salmonella* to cause enterocolitis depends on the ability of the bacteria to invade the gastrointestinal mucosa.[16,20] Invasion of the gastrointestinal mucosa occurs preferentially through specialized enterocytes called M cells that overlay intestinal lymphoid tissues such as Peyer's patches in nonequine species. A variety of enteric pathogens exploit M cells during infection of intestinal tissue.[26] Invasion of the epithelium occurs by self-induced uptake via the apical membrane of the M cell, often killing the cell in the process.[20] Salmonellae then invade neighboring cells

via the basolateral membrane, eventually spreading the destruction of the epithelium beyond the principle area of attack. Virulent salmonellae have a well-developed invasion mechanism involving generation of an apparatus called a type III secretory system that enables virulence gene products to be injected directly into enterocytes.[27] Virulence proteins injected by salmonellae into enterocytes engage the cellular machinery and induce the cell to engulf the bacteria by macropinocytosis. *Salmonella* virulence gene products also induce enterocyte chloride and fluid secretion and upregulate enterocyte transcription of inflammatory cytokines (tumor necrosis factor α and interleukin-1β) and chemokines that trigger a mucosal inflammatory response.[20,27,28]

After salmonellae invade the mucosa, they are phagocytosed quickly by macrophages and dendritic cells in the lamina propria and lymphoid tissues. The ability of salmonellae to disseminate systemically and cause enteric fever is associated with the ability to survive and proliferate in macrophages. Indeed, phagocytes have an important role in dissemination of the pathogen to blood, lymph nodes, liver, and spleen. Most salmonellae in the blood and tissues of infected animals that are competent to cause enteric fever are within phagocytic cells.[29] In adult horses with salmonellosis, dissemination appears to be limited to the intestine and mesenteric lymph nodes, and *Salmonella* rarely is cultured from blood. However, in foals and in some adults, *Salmonella* causes an enteric feverlike disease with dissemination to mesenteric lymph nodes, liver, spleen, and blood.

Salmonella organisms require specific virulence gene clusters encoded on the chromosome or on plasmids for intracellular survival in macrophages.[20] Some of these genes are sensors that signal the bacteria that it has entered an intracellular environment and turn on genes required for intracellular survival. Others, like invasion genes, are transported from the bacteria and injected into macrophage cytosol by a type III secretory system to prevent phagosome/lysosome fusion and subvert other essential macrophage killing mechanisms. Salmonellae also possess multiple genes that confer resistance to reactive oxygen and nitrogen metabolites, perhaps the most lethal antimicrobial mechanisms of macrophages.[30]

Diarrhea associated with salmonellosis has multiple causes. A *Salmonella* cytotoxin inhibits protein synthesis in mucosal cells, causing morphologic damage and altered permeability.[31] Virulent salmonellae also produce an enterotoxin similar to the heat-labile toxin (LT) produced by *Escherichia coli*.[32,33] The enterotoxin contributes to but is not required in the pathogenesis of diarrhea.[34,35] *Salmonella* enterotoxin increases secretion of chloride and water by colonic mucosal cells in many species, including horses, by increasing intracellular cyclic adenosine monophosphate concentrations.

The ability of virulent salmonellae to cause diarrhea appears to be associated most closely with the ability to invade enterocytes and to trigger an inflammatory reaction in the intestinal tissue.[20,36] Gene products injected into enterocyte cytosol by the type III secretory system of invading salmonellae stimulate chloride and fluid secretion.[27] *Salmonella* invasion of enterocytes is also a potent activator of inflammatory chemokine and cytokine production, resulting in the recruitment of leukocytes, particularly neutrophils, and activation of resident macrophages and mast cells. Products of these activated leukocytes, including prostaglandins, leukotrienes, reactive oxygen metabolites, and histamine, are potent stimulators of chloride secretion in the colon of many species.[16,37–39] The enteric nervous system integrates the diverse processes of pathogen recognition, triggering of the inflammatory response, and induction of enterocyte fluid secretion.[39]

Many of the inflammatory mediators studied stimulate colonic secretion by prostaglandin-dependent mechanisms, resulting in increased intracellular cyclic adenosine monophosphate or calcium concentrations or both in mucosal cells.[37] In addition, these mediators and the enteric nervous system may stimulate secretion by prostaglandin-independent mechanisms, inhibit sodium and water absorption, cause motility disturbances, and potentiate tissue injury, all of which enhance the pathogenicity and dissemination of *Salmonella* and contribute to the pathogenesis of diarrhea.[37,39] Neutrophils recruited to the mucosa by signals generated by the infected enterocytes physically contribute to mucosal injury by producing a variety of products that are lethal to pathogens but are also toxic to host cells.[40,41] Moreover, neutrophils attracted to infected epithelial cells accumulate beneath the monolayer, lifting it off the basement membrane in sheets. Neutrophils also migrate across the epithelial monolayer in potentially massive numbers. Transepithelial migration of neutrophils increases the permeability to macromolecules, bacterial products, and even bacteria.[41] Potentially massive losses of electrolytes, water, and protein can occur depending on bacterial and host factors. Perhaps most devastatingly, mucosal injury and altered permeability allow systemic absorption of bacterial products and dissemination of bacteria, resulting in systemic inflammatory responses such as occur with endotoxemia and septicemia.

13.13.2.1.2

Clinical Signs and Diagnosis

Four syndromes of *Salmonella* infection have been described clinically and reproduced experimentally in horses: (1) inapparent infections with latent or active carrier states; (2) depression, fever, anorexia, and neutropenia without diarrhea or colic; (3) fulminant or peracute enterocolitis with diarrhea; and (4) septicemia (enteric fever) with or without diarrhea. Inapparent infections can be activated to clinical disease in compromised horses, such as horses with colic or horses being treated with antibiotics, causing mild to severe enterocolitis. In addition, latent infections (nonshedding) can become active infections (shedding) under certain conditions, such as transportation stress and antibiotic treatment. Horses with depression, anorexia, fever, and neutropenia without diarrhea generally have a good prognosis and recover in several days without specific treatment.[42] The septicemic form is restricted mostly to neonatal foals and is uncommon in adult horses. This discussion focuses on acute enterocolitis.

Acute enterocolitis is characterized by severe fibrinonecrotic typhlocolitis, with interstitial edema and variable degrees of intramural vascular thrombosis that may progress to infarction.[1] Severe ulceration of the large intestinal mucosa may occur with serosal ecchymoses and congestion. The earliest signs of enterocolitis are usually fever and anorexia.[1,15] Signs of colic may be apparent early in the course of the disease, especially if ileus is present. Clinical signs of endotoxemia are common and range from fever, elevated heart and respiratory rates, poor peripheral perfusion, and ileus to fulminant and rapidly progressive signs of endotoxemic shock. Oral mucous membranes are often pale with perigingival hyperemia (a toxic rim) but may be brick red or cyanotic, with prolonged capillary refill time. One may note weakness, muscle fasciculations, cold extremities, and other signs suggestive of hypotensive shock; synchronous diaphragmatic flutter; abdominal pain; and significant metabolic and electrolyte abnormalities in severe cases of enterocolitis. One also may note signs of mild dehydration before diarrhea is apparent. Once diarrhea is evident, dehydration may become severe rapidly. Occasionally, horses die peracutely, without developing diarrhea.

Diarrhea may not be apparent for several days but usually occurs by 24 to 48 hours after the fever begins.[1,15] The duration of the diarrhea may be days to weeks. The character of the first diarrheal feces is usually

watery with particles of roughage but may become fluid rapidly without solid material. Finding frank blood and fibrin in the feces is unusual. The volume of feces is often large, with frequent defecation. One may note straining or signs of colic when the patient is defecating, and rectal prolapse may occur occasionally. Persistent straining and rectal prolapse may be a sign of colonic infarction. Abdominal borborygmi are often absent early in the course of the disease because of ileus but become evident later, usually when diarrhea begins. Fluid and gas sounds are commonly audible, but normal progressive motility is less frequently audible than normally. Transrectal palpation may reveal edematous rectal mucosa and colon and fluid-filled colon and cecum. One may obtain gastric reflux, especially early in the course when ileus is evident.

Hematologic abnormalities early in the course of the disease include moderate to severe neutropenia, lymphopenia, and leukopenia, a mild to moderate left shift, and toxic changes in the neutrophils.[1,15] Thrombocytopenia, moderate to severe hemoconcentration, and hyperfibrinogenemia are also common. Neutropenia is an early but nonspecific indicator of salmonellosis, often occurring concurrently with the onset of fever.[1] Later in the course of disease, one may see neutrophilic leukocytosis, indicating recovery. A degenerative left shift, with metamyelocytes and myelocytes in the peripheral blood, is a poor prognostic sign.

Serum biochemical analysis may reveal azotemia, elevations in serum sorbitol dehydrogenase and γ-glutamine aminotransferase activity, and elevated serum lactic acid concentration. Azotemia is often prerenal, but acute hemodynamic renal failure may occur in severely dehydrated, endotoxemic, or septicemic patients. Indeed, elevation of creatinine concentration is a poor prognostic indicator in horses with acute colitis.[43] Hemodynamic renal disease may be complicated by toxic injury caused by 887
administration of nephrotoxic drugs. Hyponatremia may also contribute to prerenal azotemia. Elevations in 888
hepatocellular enzymes are usually mild and reflect damage to the hepatocytes from absorbed toxins such as endotoxin and from poor perfusion caused by hypotensive shock or dehydration. Lactic acidemia may be present, reflecting poor tissue perfusion. Plasma protein rapidly drops as protein is lost in the gastrointestinal tract, causing moderate to severe hypoalbuminemia and hypoglobulinemia. Peripheral or organ edema (vascular leak syndrome) may occur if hypoproteinemia is severe, coupled with increases in endothelial permeability induced by systemic inflammation.

Hypokalemia, hyponatremia, hypochloridemia, and hypocalcemia are common electrolyte abnormalities in patients with enterocolitis. Metabolic acidosis also may be present. Coagulopathies, such as decreased antithrombin III activity and disseminated intravascular coagulation, may occur. Urinalysis may reveal isosthenuria, proteinuria, hematuria, cylindruria, and glucosuria if hemodynamic or toxic renal injury is present. The number of leukocytes in the feces usually is elevated, and occult blood may be detectable. Peritoneal fluid is usually normal except when severe mural inflammation or colonic infarction occurs.

Routine detection of salmonellae in feces involves five daily cultures of large samples (10 to 30 g) of feces using enrichment techniques.[1,44,45] However, the sensitivity of fecal culture can be as low as 30% to 50%, even if one cultures several fecal samples collected daily. Concurrent culture of rectal biopsy specimens and feces increases the sensitivity of culture techniques to 60% to 75%.[45] Currently, the polymerase chain reaction (PCR) is the most sensitive and rapid test for detecting *Salmonella* in feces. A single PCR test applied early in the course of disease is a more sensitive test for the presence of *Salmonella* than repeated fecal cultures.[46,47] Detection of salmonellae in feces does not prove a diagnosis of salmonellosis, but the positive predictive value of a positive PCR or culture results is high in horses with compatible clinical signs. Culture of peripheral blood may allow isolation of the organism if bacteremia or septicemia is present, but blood cultures are not a sensitive test for salmonellosis in adult horses. Although foals are more likely than

adults to become septicemic, culture of blood is recommended in all cases with signs suggestive of septicemia. Increased numbers of fecal leukocytes suggest an invasive process in the colon but are not specific for salmonellosis.

Early in the course of the disease, dehydration, electrolyte and acid-base imbalances, endotoxemia, and sepsis may be life threatening. Aggressive treatment during the acute stages to replace fluids lost in the diarrhea and to control sepsis and endotoxemia is often effective in controlling the primary disease. Weight loss and hypoproteinemia are often severe. Complications such as multiorgan dysfunction, vascular leak syndrome with peripheral and organ edema, laminitis, acute renal failure, venous thrombosis and septic phlebitis, irreversible protein-losing enteropathy or chronic malabsorption, pulmonary aspergillosis, and gastrointestinal infarction can occur. In many instances, horses recover from acute salmonellosis with aggressive treatment, only to succumb to complications of the disease, partially explaining the high fatality rate of equine salmonellosis compared with human salmonellosis. Chronic, mild to moderate diarrhea occasionally occurs in horses after a bout of severe salmonellosis, usually with protein-losing enteropathy. If the chronic diarrhea persists beyond 4 to 5 weeks after the onset of signs, the prognosis for recovery is poor.[15]

13.13.2.2 POTOMAC HORSE FEVER

13.13.2.2.1 Pathogenesis

Potomac horse fever (equine monocytic ehrlichiosis) is caused by the obligate intracellular rickettsial organism *Neorickettsia risticii*.[48–51] The disease is most common from late summer to early fall, with a peak incidence in July and August. Potomac horse fever was described first in the Northeast but since has been diagnosed in most areas of the continental United States, with a particularly high prevalence in the Northeast and Midwest. The geographic distribution is characterized by a significantly higher percentage of cases found along waterways and rivers.[48,49] The disease occurs sporadically, temporally and geographically, and can affect any age group of horses. The case fatality rate is 5% to 30%.[48]

Transmission of *N. risticii* has been reproduced experimentally by oral, intramuscular, intradermal, subcutaneous, and intravenous routes.[48,52] However, the natural route of infection has remained a mystery until recently. The epidemiologic data, the fact that many other rickettsial diseases are transmitted by insect vectors, and the finding that the disease can be transmitted via whole blood have implicated insect vectors in the natural transmission of the organism. Attempts to transmit the disease experimentally with ticks *(Dermacentor variablis)* or biting flies *(Stomoxys calcitrans)* have been unsuccessful.[53,54] Recently, *N. risticii* has been found to infect virgulate cercariae larval stages of trematodes that use operculate freshwater snails (*Juga* spp.) as part of their life cycle in northern California.[55] Infected virgulate cercariae have been identified in aquatic snails collected in other parts of the country as well. Virgulate cercariae are part of the life cycle of trematodes that are common parasites of many species and use freshwater snails and aquatic insects as intermediate hosts. Although the trematode species infected with *N. risticii* remains to be identified definitively, at least two species are considered potential vectors.[52] During the trematode life 888
cycle, aquatic snails release large numbers of infected cercariae into water, where they seek their next 889
intermediate host. Infected metacercaria have been identified in a variety of aquatic insects.[56] Preliminary studies suggest that *N. risticii* in fact may be transmitted via ingestion of mature caddis flies containing infected metacercariae.[57] Possibly horses are infected by drinking water containing infected cercaria

released from snails or by ingesting infected metacercariae in other aquatic insects.[52] The number of PCR-positive snails in endemic regions corresponds to the seasonal incidence of Potomac horse fever and may be as high as 26%.[58]

The pathogenesis of *N. risticii* is not understood completely. The organism infects and survives in monocytes and monocyte-derived leukocytes and can be found in blood monocytes during natural infections, but the sequence of events resulting in enterocolitis remains speculative. The organism appears first to infect blood monocytes in experimentally infected horses, which may be the vehicle of organ infection.[50,59] However, in naturally infected horses, whether leukocytes of monocytic lineage or epithelial cells are infected first is unclear. The target organ is the gastrointestinal mucosa, with the most severe lesions found in the large intestine.[59,60] Infection of human colonic cells in vitro does not cause major cytopathologic effects for several days. Disruption of the microvilli in the region of the plasma membrane where sodium chloride channels are located has been observed in human colonic cell cultures.[61] Infection in horses is associated with variable degrees of morphologic damage.[59,60] Mild morphologic damage and mononuclear cell infiltration of the lamina propria occur early during the infection, but fibrinous, necrotizing typhlocolitis with severe mucosal ulceration and inflammation of the lamina propria may occur later in the disease. Vasculitis and intravascular coagulation are consistent features in the large intestine, with perivascular edema.[60] One can observe *N. risticii* in mucosal cells and macrophages and mast cells of the lamina propria.[59,60] *N. risticii* can survive and multiply in macrophages by inhibiting the production of reactive oxygen intermediates and by avoiding lysosomal digestion by blocking phagosome-lysosome fusion.[62–64]

Evidence of impaired sodium chloride absorption in the colon has been suggested to contribute to diarrhea in infected horses and may be related to destruction of the enterocyte membrane structure in the region of sodium chloride channels.[61,65] Direct injury to the mucosa by *N. risticii* and colonic inflammation are likely to be prominent features leading to diarrhea, especially later in the disease.[60] Fluid, protein, and electrolyte loss likely is caused by mucosal injury and effects on enterocyte fluid secretion caused by the inflammatory response. Like other inflammatory conditions of the colon, systemic inflammation caused by absorption of bacteria and bacterial products is a potential complication of *N. risticii* infections if mucosal injury is severe, which contributes to the clinical signs seen during the disease.

13.13.2.2.2

Clinical Signs and Diagnosis

N. risticii infection is clinically similar to other forms of enterocolitis and is characterized by anorexia, depression, and fever.[48,60,66] Experimental infections produce a biphasic fever occurring 6 to 7 days apart. Decreased gastrointestinal motility, manifested as reduced borborygmi, occurs during the early stages before the onset of diarrhea. Diarrhea occurs in 75% of cases and occurs 2 days after the second fever episode during experimental infections.[66,67] The diarrhea can be moderate to severe and dehydrating. Ileus can develop at any stage of the disease and can cause signs of moderate to severe colic. Systemic signs of endotoxemia, shock, and peripheral edema may occur and are similar to those described for salmonellosis. Experimental and natural infection with *N. risticii* can cause abortion of infected fetuses in pregnant mares.[68,69] Laminitis is a complication in 20% to 30% of naturally occurring cases and is often severe. Other complications include protein-losing enteropathy, thrombosis, and renal failure, as described for salmonellosis.

Hematologic abnormalities reflect endotoxemia, dehydration, and sepsis and are essentially identical to those described for salmonellosis. Neutropenia with a left shift is a consistent feature and occurs concurrently with or soon after the onset of diarrhea. Thrombocytopenia is common and often severe.[67] Neutrophilic leukocytosis occurs later in the course of the disease. Hyperfibrinogenemia is usually more pronounced than that with salmonellosis. Serum electrolyte, acid-base, and biochemical abnormalities are also similar to those described for salmonellosis. Coagulopathies are common during *N. risticii* infection and reflect activation of coagulation pathways. Disseminated intravascular coagulation is common and may be related to the high frequency of laminitis associated with *N. risticii* infection.[70]

One cannot base diagnosis of *N. risticii* infection solely on clinical signs because the disease is clinically similar to other forms of enterocolitis. However, in endemic areas, acute colitis is likely to be caused by *N. risiticii,* and thus the clinical signs of acute inflammatory colitis in fact may have a high predictive value. Serologic evidence of infection, such as rising antibody titers to *N. risticii* detected by indirect immunofluorescence or enzyme-linked immunosorbent assay in paired serum samples may be helpful in establishing a diagnosis.[49,71] One should take care when interpreting the indirect immunofluorescence serologic test for *N. risticii* because the test appears to have a high false-positive rate.[72] Culture of the organism from blood is possible but is difficult and is generally useful only in the research laboratory. 889
Recently developed polymerase chain PCR tests for *N. risticii* DNA are rapid, highly sensitive (as sensitive 890
as culture), and specific for *N. risticii* infection and can be applied to blood or feces.[73–75]

13.13.2.2.3 Prevention

Prevention of the disease by reducing exposure to the causative organism is difficult because the mode of transmission is not known. A killed vaccine has been developed that is effective in preventing clinical illness other than fever in 80% of experimentally challenged horses using the vaccine strain. However, field studies suggest the vaccine has limited benefit for prevention or decreasing the severity of natural infection. Vaccine failures have been attributed to strain differences in antigenicity or to poor antibody responses to the vaccine.[76,77]

13.13.2.3 EQUINE INTESTINAL CLOSTRIDIOSIS

13.13.2.3.1 Pathogenesis

Clostridiosis is an important cause of acute enterocolitis in foals and adult horses. *Clostridium perfringens* and *C. difficile* are associated most commonly with intestinal clostridiosis in horses, but other clostridial species, including *C. septicum, C. cadaveris,* and *C. sordellii* also have been isolated from horses with enterocolitis.[78–83] In horses of all ages, clostridial enterocolitis appears to be a common antibiotic-associated and nosocomial cause of enterocolitis.[82,84,85] However, clostridiosis in neonatal foals is a distinct clinical entity and is discussed in more detail elsewhere. This chapter focuses on adult intestinal clostridiosis.

Clostridia are obligate anaerobic to aerotolerant spore-forming gram-positive rods that are ubiquitous in the environment in the spore form.[83] Clostridia are elements of the normal flora of horses of all ages and are among the first bacteria acquired after birth. However, clostridia inhabiting the gastrointestinal tract

normally are found in low numbers and do not produce enterotoxins. Clostridiosis is associated with an increase in the number of a particular species of clostridia in the gastrointestinal tract and, perhaps most importantly, exotoxin production. Although the conditions resulting in exotoxin production are not understood fully, several factors increase clostridial numbers in the gastrointestinal tract. Dietary factors are known to affect the numbers of *Clostridium* species shed in the horse feces.[78] Experimental induction of colic increases fecal shedding of *Clostridium* species in the absence of diarrhea.[86] Antibiotics, particularly administered orally or recycled via the enterohepatic system, are well documented to increase the recovery of clostridia colony-forming units (CFUs) in equine feces and may result in clinical clostridiosis.[79,81,87–90] Indeed, clostridiosis associated with *C. perfringens* or *C. difficile* is likely to be the most important cause of antibiotic-induced enterocolitis in the horse.

13.13.2.3.1.1

Clostridium perfringens

C. perfringens is made up of many genetically distinct strains of variable virulence that produce one or more of a large group of exotoxins. The pattern of exotoxin production is used to classify *C. perfringens* into five types, A, B, C, D, and E. *C. perfringens* type A is the most common clostridium isolate from healthy horses of all ages and adults and foals with diarrhea worldwide. *C. perfringens* types A, B, C, and D have been associated with hemorrhagic enteritis in foals less than 10 days of age, with type C being the most common cause in North America.

The primary toxin produced by *C. perfringens* type A is α-toxin (phospholipase C), which interferes with glucose uptake and energy production and activates arachidonic acid metabolism and signaling pathways in enterocytes.[83] Oral administration of α-toxin does not cause tissue necrosis but causes increased secretion by small intestinal mucosal cells in human beings.[91,92] The β-toxin of types B and C is a cytotoxin that causes enterocyte necrosis, ulceration, and ultimately severe intestinal inflammation and hemorrhage.[93] A novel toxin designated β2 may also have a role in *C. perfringens* enterocolitis.[94] The biologic activity of the β2-toxin is similar to β-toxin, but β2-toxin is not related to β-toxin in sequence. The β2-toxin was prevalent in two groups of horses with acute enterocolitis but not in healthy horses.[95] The β2-toxin appears to be associated predominantly with *C. perfringens* that would have been classified otherwise as type A but that in fact may represent a previously undescribed type.

Virulent strains of *C. perfringens* type A and to a lesser extent type C also may produce enterotoxin. Enterotoxin is a cytotoxin that inserts into cell membranes to form pores, which alter permeability to water and macromolecules and ultimately lead to cellular necrosis.[96] Massive desquamation of the intestinal mucosa resulting from enterotoxin cytotoxicity triggers an inflammatory response, intestinal edema, mural hemorrhage, and systemic inflammation.[97] Enterotoxin also alters tight junction integrity, resulting in increased paracellular permeability by a noncytotoxic mechanism.[98]

13.13.2.3.1.2

Clostridium difficile

C. difficile produces several toxins, but only two, toxin A and toxin B have been studied in detail. Toxin B is a potent cytotoxin in vitro, but its role in enterocolitis is less clear than the role of toxin A. Toxin B does not induce fluid secretion, inflammation, or characteristic alterations in intestinal morphology.*C. difficile* induces an inflammatory response with hypersecretory diarrhea that is induced in large part by the enterotoxin toxin A.[99] Toxin A induces neutrophil influx into intestinal tissue, mast cell

degranulation, and secretion of prostaglandins, histamine, cytokines, and 5-hydroxytryptamine by these activated leukocytes.[100,101] The products of neutrophils and mast cells have a prominent role in the vasodilatory and secretory responses in the intestine during *C. difficile* infection. 890 891

The enteric nervous system is central to the induction of intestinal inflammation and mucosal secretion by toxin A. A model for toxin A–induced secretory diarrhea has emerged in which toxin A stimulates substance P–containing afferent sensory nerve fibers, which in turn stimulate mast cell degranulation, recruitment and activation of polymorphonuclear leukocytes, and vasodilation.[102–104] Toxin A–induced stimulation of enterocyte secretion can occur via secretomotor neuronal stimulation by substance P–containing sensory neurons or products of mast cells and polymorphonuclear leukocytes. Neural blockade or depletion of substance P abolishes mast cell degranulation, polymorphonuclear leukocyte influx, and enterocyte secretion. How toxin A triggers the sensory component of the enteric nervous system is not known yet, but toxin A–induced necrosis of enterocytes likely exposes afferent neurons to the noxious milieu of the intestinal contents.

13.13.2.3.2 Clinical Signs and Diagnosis

Equine intestinal clostridiosis is clinically similar to other forms of acute enterocolitis in horses.[78,83] Although the clinical course is usually acute, peracute colitis with rapid death may occur. Occasionally, a milder, more prolonged clinical course occurs. One may note fever, anorexia, and depression before the onset of gastrointestinal signs, but more commonly no prodromal signs are apparent. Signs of endotoxemia and shock may accompany acute signs of colic and severe, dehydrating diarrhea. Diarrhea may not be profuse but is usually dark and foul smelling. Like the clinical signs, hematologic and serum biochemical abnormalities are similar to those associated with other forms of enterocolitis and reflect fluid, protein, and electrolyte loss and systemic inflammation from endotoxemia. Neutropenia, leukopenia, and hemoconcentration are common. Hypoproteinemia may be profound. One often may note hyponatremia, hypokalemia, hypochloremia, hypocalcemia, and a mixed prerenal/renal azotemia, as well as metabolic acidosis and coagulopathies. Serum concentrations of hepatocellular enzymes such as sorbitol dehydrogenase may be elevated, and liver function may be reduced.

Preliminary diagnosis of equine intestinal clostridiosis caused by *C. perfringens* is based on the isolation of greater than 100 CFUs of *C. perfringens* type A per gram of feces from patients with diarrhea and signs suggestive of toxemia. Similar criteria are used to screen human patients for *C. perfringens* type A infection. Normal horses shed fewer than 100 CFUs/g of feces, and usually horses with intestinal clostridiosis shed greater than 1×10^6 CFUs/g.[78,105] However, identification of increased numbers of *Clostridium* organisms in the feces does not prove infection. Detection of *C. perfringens* toxins in feces or intestinal contents in horses with increased numbers of fecal CFUs and clinical signs of enterocolitis is more conclusive evidence of an enterotoxigenic infection than culture alone. Immunoassays are available that are primarily designed to detect *C. perfringens* enterotoxin.[83] However, the reliability (specificity) of some immunoassays for diagnosis of *C. perfringens* infection has come into question. Recently, PCR multiplex and gene probe assays have been developed to detect the major lethal toxins in isolates or fecal samples to determine the pattern or toxin production and are currently the preferred methods of detection.[106–108]

As for *C. perfringens,* diagnosis of *C. difficile* infection consists of culture of the organism from feces and identification of toxins in the feces. Bacterial culture of *C. difficile* may be difficult and may be an insensitive test in horses.[109–110] Detection may require enrichment techniques and culture of multiple fecal

samples.[110,111] Detection of toxins A and B in feces is regarded as the preferred test for diagnosis of *C. difficile* infection in human beings.[83] Commercial enzyme-linked immunosorbent assays are available for toxins A and B that are specific and appear to be more sensitive than a single culture for identifying *C. difficile* infection in adult horses.[109,110] One also may induce toxin production by *C. difficile* isolates. Sensitive PCR methods also have been developed for application to fecal samples and isolates to detect the genes for toxins A and B.[83]

13.13.2.4 PROLIFERATIVE ENTEROPATHY

13.13.2.4.1 Pathogenesis

Proliferative enteropathy is a chronic hyperplastic disorder of the small intestine and has been described in a variety of mammalian and avian species.[112,113] The only causative agent identified to date that induces proliferative enteropathy is the obligate intracellular pathogen *Lawsonia intracellulare*.[113,114] The pig is the most frequently naturally affected species. However, the reports of equine proliferative enteropathy associated with *L. intracellulare* have increased in recent years.[115–118] The relatedness of the strains of *L. intracellulare* causing proliferative enteropathy in pigs and horses or even among other affected species is not known. No host restriction is apparent because hamsters and other rodents can be infected with porcine strains of *L. intracellulare*. Before the year 2000, reports of proliferative enteropathy in the literature describing isolated cases were sporadic.[116–118] However, since 2000, outbreaks on breeding farms have been documented on farms in Canada, suggesting that a new strain has emerged.[115]

The mode of infection is fecal-oral, and infected animals can shed large numbers of organisms in feces.[113] 891
892 Affected animals shedding the organism in the feces serve as a source of infection for herdmates. Possibly nonequine species serve as reservoirs contributing to outbreaks on horse farms. Factors that increase the risk of proliferative enteropathy in pigs include overcrowding, ration changes, transport, and weaning.[113,114] Like pigs, horses are affected as weanlings. Factors associated with weaning and other stresses may affect immunity and increase susceptibility to infection. The incubation period is 2 to 3 weeks in nonequine species and is presumed to be similar in horses.

Experimental *L. intracellulare* infection produces characteristic pathologic lesions in pigs and hamsters that are identical to lesions in horses with proliferative enteropathy.[113,114] A profound hyperplasia of the mucosa predominantly caused by proliferation of crypt epithelium and crypt hyperplasia is induced locally in infected islands of tissue and eventually extends to the entire distal jejunum and ileum. *L. intracellulare* preferentially infects proliferating cells, thus the tropism for the crypt epithelium. Infected cells proliferate far more rapidly than uninfected cells, suggesting that *L. intracellulare* directly induced the proliferative response. However, the molecular basis for the enhanced proliferation is not known. *L. intracellulare* penetrates epithelial cells in a membrane-bound vesicle but eventually escapes the vacuole and is found free in the cytoplasm concentrated at the apical pole of the cell.

The gross pathologic lesions found in equine proliferative enteropathy are characteristic.[115–118] Lesions may be segmental and typically are found in the ileum and terminal jejunum in horses. However, lesions also may affect the duodenum. Severe mucosal hypertrophy often occurs but may wane during the chronic stages of the disease. The mucosa may become corrugated with focal erosions or ulcers. One often can identify submucosal edema easily on cut sections of affected segments. Moderate to severe crypt

hyperplasia with atrophy of the intestinal villi is a consistent feature. The hyperplastic crypts are branched and may herniate into the submucosa. Necrosis, edema of the submucosal and lamina propria, hemorrhage, mononuclear inflammation and muscular hypertrophy have been reported in affected intestinal segments but are not consistent. Special stains such as silver stain are required to detect intracellular organisms. The organisms are curved or comma-shaped rods found clustered in the apical cytoplasm of hyperplastic crypt epithelium.

The proliferative response of the intestinal mucosa alters absorption of nutrients and fluid secretion by disrupting the architecture of the villi and by altering the maturation of epithelial cells into absorptive cells, accounting for the secretory diarrhea and often severe weight loss.[112,114] The combined effects of the inflammatory response and malabsorption may account for the protein-losing enteropathy.

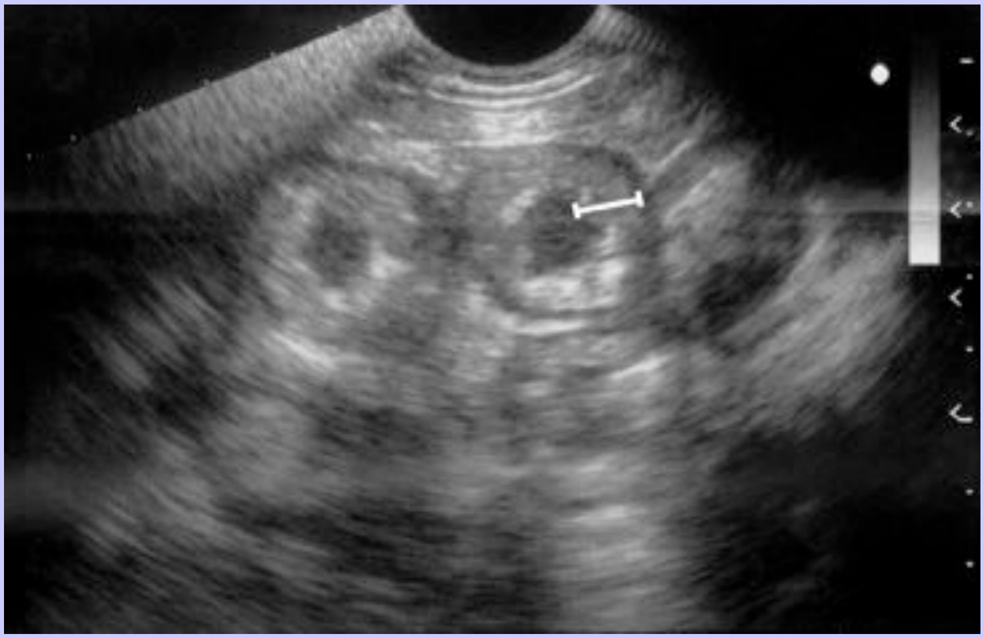
13.13.2.4.2 Clinical Signs and Diagnosis

Proliferative enteritis most commonly affects weanling foals ages 4 to 6 months. The clinical signs of proliferative enteropathy include ill thrift, weight loss, peripheral edema, diarrhea, and colic.[115–118] The diarrhea is usually in the form of soft feces but may be profuse and watery. Some foals with mild diarrhea have black, tarry feces. Secondary complications such as gastric ulceration, bronchopneumonia, or parasitism may occur concurrently with the proliferative enteropathy. Clinicopathologic features include mild to moderate anemia, moderate to severe hypoalbuminemia (often <2 g/dl), hypoglobulinemia, neutrophilic leukocytosis, and hyperfibrinogenemia. Creatine kinase activities may be elevated in affected foals. Prerenal azotemia and electrolyte imbalances such as hyponatremia may be associated with diarrhea. Peritoneal fluid analysis is usually unremarkable. Ultrasonographic examination of the small intestine often reveals significant thickening of the intestinal wall (Figure 13.13-1). Intestinal edema may be evident as a hypoechoic appearance to one or more layers of the intestinal wall.

Methods for antemortem diagnosis include serologic analysis of *L. intracellulare* antibodies and PCR analysis of feces.[115] Serologic analysis using an indirect immunofluorescent antibody test may be the most useful single test available. The PCR test is specific but the sensitivity may be low. By the time clinical signs appear, 90% of pigs are serologically positive for anti–*Lawsonia intracellulare* immunoglobulin G (IgG). In contrast, only 37% of pigs had positive fecal PCR tests.[119] Of the seven foals tested in an outbreak of equine proliferative enteropathy,[115] four foals with confirmed disease and three with suspected 892

893 proliferative enteropathy had serologic titers against *L. intracellulare* of 1:30 or greater. In contrast, serum samples collected from 72 foals before the outbreak were negative for *L. intracellulare* antibodies. Fecal PCR for *L. intracellulare* was positive in 6 of 18 foals tested, and half of the serologically positive foals had negative fecal PCR tests. Many clinicians combine serologic analysis with fecal PCR testing to increase the sensitivity and specificity of these diagnostic methods. Isolation and culture of the organism requires cell culture techniques that are not widely available. Thus no practical method exists for culturing the organism from feces or tissues that is available for clinical use.

Figure 13.13-1 Ultrasonogram of the small intestine in a weanling foal with weight loss, diarrhea, and hypoproteinemia. The extreme mural thickening of the small intestine *(bar)* is typical of proliferative enteropathy.



Definitive diagnosis requires histopathologic examination of affected tissues.[112] Diagnosis is based on typical histopathologic findings of mucosal hypertrophy and submucosal edema and identification of small, curved, rod-shaped intracellular bacteria at the apical pole of epithelial cells in affected segments of intestine. Special stains such as Warthin-Starry silver stain are required to detect the bacteria in histopathologic specimens. PCR analysis of affected intestinal tissue is a specific test for the presence of *L. intracellulare* and, unlike fecal PCR analysis, appears to be sensitive.[120]

13.13.2.5 STRONGYLOSIS

13.13.2.5.1 Pathogenesis

Strongyle infections in horses are caused by two groups of nematodes: large and small strongyles (see the section Cyathostomiasis). Large strongyles that are pathogenic in horses include *Strongylus vulgaris, S. edentatus,* and *S. equinus*. Of these species, *S. vulgaris* is by far the most important cause of disease in the large intestine and in fact is the most pathogenic parasitic infection in horses. *S. vulgaris* infection in horses is manifested clinically by two forms: acute and chronic disease.[121] The age and resistance of the host, the infective dose, and the size and function of the affected arteries influence the type and degree of disease that occurs. Sudden ingestion of large numbers of infective larvae by a naïve host causes acute strongylosis, whereas ingestion of fewer infective larvae over a long period of time by an older, more resistant host

causes chronic strongylosis. Acute strongylosis is more likely to cause colic than diarrhea and may be rapidly fata l. Chronic strongylosis tends to cause debilitation and signs of colic but may also cause diarrhea.

Diarrhea associated with acute strongylosis occurs within several days of infection and is likely to be caused by migration of the larvae through the intestinal wall. Fourth-stage larvae migrate through the mucosa and submucosa into the arterioles of the intestine, causing mural edema, hemorrhage, and infiltration with inflammatory cells into the intestinal wall.[121,122] Increased secretion and decreased absorption of fluid and electrolytes, stimulated by inflammatory mediators such as prostaglandins and histamine, may play a role in the diarrhea induced by *S. vulgaris*. Interstitial edema and damage to the interstitial matrix and mucosa may result from inflammation and migration of the parasites, causing increased secretion of fluid and albumin loss. Abnormal gastrointestinal motility also may play a role in the development of diarrhea. Migration of larvae through the intestinal wall early in the course of infection affects myoelectric activity and motility in the large intestine and may affect retention of ingesta and absorption of fluid.[123,124] The cause of death in acute strongylosis has not been addressed but may be related to massive migration through the vasculature, causing thrombosis with ischemia and infarction of the intestine.

Chronic strongylosis causes typical verminous arteritis and is associated more commonly with natural infections in horses than with acute strongylosis.[121] Lesions of the large intestinal vasculature caused by migration of larvae through the intima are characterized by thrombus formation, narrowing of the arterial lumen, fibrosis, and thickening of the arterial wall.[121,122] Embolization may occur, causing acute segmental infarction of the large intestine, but more commonly reduced blood flow without embolization causes ischemia and occasionally infarction.[122,125] Postmortem examination of horses with colonic infarction failed to reveal embolization as the cause in most cases.[125] Reduced blood flow in the tissues of the intestine usually results from narrowing of the arterial lumen by the thrombus and formation of microthrombi at sites independent of the parasites. Release of vasoconstrictive inflammatory mediators such as leukotrienes from platelets, neutrophils, and eosinophils and elaboration of parasitic antigens or toxins may cause vasoconstriction and ischemia.[126] Horses with experimental strongylosis were found to have a 50% reduction of blood flow in the colonic vasculature.[127]

Clearly, reduced blood flow is an important effect of chronic strongylosis, but the relationship between blood flow and diarrhea is unclear. Disrupted motility resulting from ischemia may lead to diarrhea by reducing the retention of ingesta and absorption of fluid. Acute infarction and mucosal ulceration have been found to cause severe chronic diarrhea in naturally infected horses.[128] Release of inflammatory mediators such as prostaglandins, histamine, and kinins from inflammatory cells associated with thrombi and inflamed intestine also may affect secretion, absorption, and motility, leading to diarrhea.

13.13.2.5.2 Clinical Signs and Diagnosis

The clinical signs of acute strongylosis caused by *S. vulgaris* infection are characterized by depression, moderate to severe colic, and fever.[129] Diarrhea is less often a feature of acute strongylosis than is colic.[121] Most cases of acute strongylosis occur in young, naïve horses that are introduced to an infested environment or are inoculated experimentally with infective larvae. This form of strongylosis often is not recognized naturally. Chronic strongylosis, however, occurs most commonly as a natural syndrome. Weight loss or poor weight gain; chronic, intermittent colic; fever; poor appetite; and diarrhea are frequent signs.[121,122] Diarrhea may be profuse and watery, or the feces may be soft but of normal volume. Transrectal palpation

893
894

may reveal thickening and fremitus in the cranial mesenteric artery. Young horses are most commonly affected, but older horses also may be affected. Horses with acute infarction or large intestinal ulceration following chronic strongylosis may have signs of severe abdominal pain, sepsis, and endotoxemia, and profuse, watery diarrhea is common.

Hematologic abnormalities associated with strongylosis include neutrophilic leukocytosis and eosinophilia.[129–131] Neutrophilia appears to be an early event during the course of the disease, and eosinophilia tends to appear later.[129,131] Hyperfibrinogenemia also may occur, especially later in the course of the disease. Serum α- and β-globulin and IgG(T) concentrations are characteristically elevated.[130–132] Horses with chronic ulcerative colitis following strongylosis may exhibit severe hypoalbuminemia.[128] Peritoneal fluid analysis may reveal an elevated protein concentration and eosinophilia.[130,131] Tentative diagnosis is based on clinical signs, hematologic abnormalities, and peritoneal fluid analysis. Elevated serum α- and β-globulin concentrations and IgG(T) concentration support the diagnosis.[132] Fecal analysis may reveal strongyle eggs, but fecal egg counts are often unreliable because nonpatent larvae cause the disease.

13.13.2.5.3 Prevention

Appropriate preventive measures are important in controlling this disease, including management procedures such as preventing overcrowding, reducing exposure of susceptible individuals, and instituting proper deworming schedules. Ivermectin is the preferred anthelmintic used to control strongylosis in horses. Monitoring fecal egg counts as a means of evaluating the efficacy of parasite control measures is recommended.

13.13.2.6 CYATHOSTOMIASIS

13.13.2.6.1 Pathogenesis

Infection with small strongyles (cyathostomiasis) is well recognized as a cause of diarrhea and large intestinal disease in horses of all ages.[133–138] Clinical disease is caused by intramural larval stages. The cyathostome life cycle requires migration by fourth-stage larvae through the mucosa of the large intestine and may include a period of hypobiosis during which the larvae remain encysted within the mucosal layer of the large intestine. After a period of hypobiosis the larvae emerge in response to a largely unknown stimulus. Most cases occur when larval emergence takes place, classically in the late winter and spring in the northern temperate zones when larvae are expected to emerge and in the late fall or winter months in the southeastern United States and subtropical regions.[133] Sudden emergence of encysted larvae causes the mucosal injury, ulceration, and inflammatory reaction responsible in large part for the clinical disease.[133,139] However, migration of the larvae as they penetrate the mucosa affects motility patterns and can cause inflammation that may contribute to diarrhea.[139] Chronic, eosinophilic, granulomatous colitis and diarrhea with histopathologic evidence of hypobiotic cyathostome larvae in the large intestine have been reported in two horses during a period in which emergence of larvae would not be expected to occur (early winter).[133]

Natural emergence of cyathostome larvae causes fibrinous inflammation of the large intestine, focal necrosis, mural hemorrhage, and ulceration of the large intestinal mucosa, which even may result in bleeding into the lumen. Mild to moderate eosinophilic and mononuclear inflammation of the lamina

propria occurs, and moderate to severe interstitial edema frequently occurs.[122,139] Colonic inflammation and interstitial edema may contribute to the diarrhea, along with the loss of the mucosal barrier, by causing increased active and passive secretion of fluid, electrolytes, and protein. Protein loss is often significant, resulting in profound hypoalbuminemia and interstitial edema of skin and other organs. Chronic, granulomatous colitis has been reported to occur in response to encysted larvae and may cause diarrhea by increased secretion following granulomatous inflammation or disruption of the interstitium by granulomatous infiltration. Administration of an anthelmintic to horses with a heavy load of encysted larvae also may cause rapid larval death and acute and often severe inflammation similar to natural emergence.

13.13.2.6.2 Clinical Signs and Diagnosis

Cyathostomiasis may be the most commonly identified cause of chronic diarrhea in the horse.[140–142] However, an acute syndrome also has been associated with cyathostomiasis.[138] Clinical signs of cyathostomiasis are characterized by moderate to severe weight loss or poor weight gain, ill thrift, ventral edema, intermittent fever, and intermittent, mild colic. Acute onset of diarrhea is typically profuse and progresses to chronic diarrhea that is often mild, is the consistency of bovine feces, and may be intermittent.[133–138,142] Appetite is usually normal, but affected horses occasionally have a ravenous appetite. Transrectal palpation usually does not reveal any abnormalities. Cyathostomiasis may affect any age of 894
horse, and clinical signs are more common during periods of emergence of larvae, corresponding to late 895
winter and spring in northern temperate zones. The deworming history may appear to be adequate.

Neutrophilic leukocytosis is typically evident, but the white blood cell count may be normal.[133–138] Profound hypoalbuminemia is a characteristic feature of cyathostomiasis, manifested clinically by ventral edema. Plasma α- and β-globulin concentrations may be elevated, which can result in a normal total plasma protein concentration in spite of hypoalbuminemia.[134–136] The serum IgG(T) concentration, however, has been reported to be normal, which may help distinguish cyathostomiasis from *S. vulgaris* infection.[133,135,136] In addition, peritoneal fluid analysis does not usually reveal any abnormalities, in contrast to horses with *S. vulgaris* infection. Fecal analysis may be unrewarding because the infection is often not patent when clinical signs are apparent. Measurement of plasma fructosamine may provide a measure of protein catabolism or protein loss in the absence of hypoalbuminemia. Plasma fructosamine concentrations are significantly lower in horses with experimental cyathostomiasis than in normal controls,[142,143] suggesting that this test may be a useful diagnostic tool. However, the test has not yet been validated in naturally occurring cases, and neither the specificity nor the sensitivity is known. Rectal scrapings or rectal mucosal biopsies may reveal evidence of cyathostome larvae.[133,136] Definitive diagnosis usually requires microscopic examination of biopsy specimens of the cecum and ascending colon, collected by laparotomy. Examination of biopsy specimens collected from the small intestine is recommended to rule out other causes of weight loss and diarrhea. One should include appropriate diagnostic tests, such as culture of feces for pathogenic bacteria, in the workup to rule out other causes.

13.13.2.6.3 Prevention

Preventive measures are appropriate for other horses on premises known to have a problem with cyathostomiasis, particularly frequent deworming (every 6 weeks) during times of high infectivity (spring and summer in the north and fall, winter, and early spring in the south) to eliminate parasites before they become patent.[133] Because of high levels of resistance to benzimidazoles, avermectins (ivermectin or

moxidectin) are the drugs of choice.[144–146] Resistance to ivermectin has been demonstrated, but the prevalence of ivermectin resistance appears to remain low.[144] Although daily pyrantel pamoate administration also has been reported to reduce worm burdens and pasture infectivity in young and mature horses effectively,[147] cyathostome resistance has been reported and is a concern for the use of this drug as a routine preventive anthelmintic.[145,148]

13.13.3 Toxicologic Diseases

Diarrhea in adult horses may also occur secondary to administration of antimicrobial or antiinflammatory medications or after ingestion of toxic compounds. Affected horses exhibit clinical signs that may be indistinguishable from signs exhibited by horses with diarrhea of infectious etiology.

13.13.3.1 ANTIBIOTIC-ASSOCIATED DIARRHEA

13.13.3.1.1 Pathogenesis

Antibiotic-associated diarrhea has been reported in many species, including horses.[149] Certain antibiotics—such as trimethoprim-sulfonamide combinations, erythromycin, penicillins, tetracyclines, clindamycin, and lincomycin—are associated with naturally occurring and experimental enterocolitis syndromes in horses.[79,149–152] In some cases, such as with trimethoprim-sulfonamide combinations, the geographic incidence of antibiotic-associated diarrhea appears to differ considerably.

Clostridium perfringens, C. difficile, and *Salmonella* spp. are apparently the most common causes of antibiotic-associated diarrhea in horses. Outbreaks of *C. difficile* have been reported in hospitalized horses being treated with antibiotics.[81,85] In Sweden, accidental erythromycin ingestion has been associated with *C. difficile* enterocolitis in mares in which their foals were being treated for *Rhodococcus equi*.[89,151,153] Interestingly, this phenomenon has not been reported in other areas of the world. Foals being treated with erythromycin are at a higher risk for diarrhea than foals being treated with other antibiotics. Tetracycline administration has been shown to be associated with an increase in the numbers of gram-negative enteric bacteria and *C. perfringens* in the feces of horses and reactivation of salmonellosis and prolongation of fecal shedding of *Salmonella*.[78,154]

The most common mechanism by which antibiotics cause diarrhea is by disrupting the gastrointestinal flora. The normal large intestinal flora, comprised of mainly obligate anaerobes and streptococci, protects the host from pathogenic bacteria by colonization resistance.[17] Ecologic factors play an important role in colonization resistance. For example, surface bacteria in the large intestine interact with receptors on the mucosal cells, facilitating adherence to the mucosa.[17,155] In doing so, the normal organisms compete more successfully for this important niche. Competition for space and nutrients is an important means of preventing colonization and proliferation of pathogenic bacteria. In addition, anaerobic bacteria produce short-chain fatty acids (SCFAs) and other metabolites that are toxic to facultative anaerobic bacteria, especially in the conditions of the large intestine.[16,17,155] Organisms of the normal flora also produce bacteriocins that inhibit growth of potential pathogens.[16] 895

896

Antibiotics that deplete the population of obligate anaerobes and streptococci efficiently decrease colonization resistance.[16] Production of fatty acids diminishes, thus reducing competition for space and

nutrients. As a result, gram-negative enteric bacteria such as *Salmonella* are able to proliferate. In addition, pathogenic anaerobes normally found in low numbers can proliferate. Antibiotic-resistant strains of bacteria, especially gram-negative enteric bacteria and possibly clostridia, may be selected by antibiotic administration, allowing proliferation of pathogenic bacteria resistant to many antibiotics.[156] Obligate anaerobic commensal organisms, perhaps the most critical group of microbes for maintaining colonization resistance, are usually susceptible to macrolides, tetracyclines, β-lactams, and lincosamides, perhaps explaining the high incidence of diarrhea associated with the administration of these antibiotics.[83]

In addition to reduction of colonization resistance, depletion of the normal anaerobic microbial population in the intestine decreases carbohydrate fermentation and production of SCFAs, which contributes to the pathogenesis of antibiotic-associated diarrhea by decreasing absorption of sodium and water by the colonic mucosa.[157] Ampicillin decreases colonic fermentation of carbohydrates in human beings.[158] Human patients with antibiotic-associated diarrhea have greatly impaired colonic fermentation and low production of SCFAs. Erythromycin, ampicillin, or metronidazole treatment is associated with decreased production of SCFAs in patients with and without diarrhea.[88] Absorption of sodium and water is stimulated by absorption of SCFAs in the equine colon, suggesting that reduction of colonic SCFA content by antibiotic-induced depletion of anaerobic flora has similar effects in horses as in human beings.[157]

Broad-spectrum antibiotics exert a more profound effect on the gastrointestinal flora than narrow-spectrum antibiotics. Antibiotics administered orally, especially those that are poorly absorbed, are more likely to cause diarrhea than are parenterally administered antibiotics. For instance, clindamycin is less likely to cause diarrhea in human beings when administered intravenously than when administered orally. Antibiotics with extensive enterohepatic circulation, such as tetracyclines and erythromycin, are excreted in high concentrations in the bile and are associated more commonly with diarrhea than antibiotics that do not undergo enterohepatic circulation.[159]

Antibiotics may cause diarrhea by means other than by disrupting the normal flora. Direct toxic effects may play a role in producing irritation, increasing secretion, and disrupting motility patterns. Tetracyclines are irritating to the gastrointestinal mucosa and may cause inflammation and increase secretion.[159] Erythromycin has been shown to interact with smooth muscle cells, stimulating gastrointestinal motility.[159,160] Normal peristalsis plays an important role in suppressing the population size of potentially pathogenic bacteria. Normally, bacteria that are prevented from adhering to the mucosa by colonization resistance are swept aborally by peristalsis and are excreted in the feces. Disruption of normal motility patterns may prevent clearance of pathogenic bacteria, contributing to the colonization of mucosal surfaces.

13.13.3.1.2 Clinical Signs and Diagnosis

Diarrhea induced by antibiotics usually occurs within 7 days of antibiotic administration or can occur several days after cessation of antibiotic treatment. The clinical syndrome of antibiotic-associated diarrhea can vary from mild diarrhea to fulminant enterocolitis with severe diarrhea. Mild cases of diarrhea are common, especially in foals receiving erythromycin, trimethoprim-sulfonamide combinations, or rifampin.[151,161] Mild cases of diarrhea are usually not clinically significant. However, acute, severe enterocolitis can occur in all ages of horses receiving antibiotics and can be life threatening. Clinical signs are identical to other causes of acute enterocolitis. Severe, dehydrating diarrhea, endotoxemia, sepsis, and shock may occur. Hemoconcentration, neutropenia, hypoproteinemia, and electrolyte and acid-base imbalances are common. Severe hyponatremia may occur in foals with antibiotic-associated diarrhea, especially if trimethoprim-

sulfonamide and rifampin combinations are the cause.[161] More detailed descriptions of the clinical and laboratory findings were given previously. Diagnosis is presumptive, because definitive diagnosis of antibiotic-associated diarrhea is impossible. Fecal culture and PCR testing may reveal *Salmonella* or *Clostridium* infection.

13.13.3.2 NONSTEROIDAL ANTIINFLAMMATORY DRUGS

13.13.3.2.1 Pathogenesis

Toxicity resulting from nonsteroidal antiinflammatory drug (NSAID) administration has been well documented in several species, including horses.[162–168] In horses and human beings, NSAID toxicity is manifested by renal and gastrointestinal disease. Elderly human patients are more susceptible to NSAID toxicity, but the effects of age on NSAID toxicity in horses are less well defined. Foals are considered to be more susceptible than adult horses to gastrointestinal disease following NSAID administration, and ponies may be more susceptible than horses. All NSAIDs are capable of inducing gastrointestinal and renal damage at toxic concentrations, and the toxicity is not significantly different among products. Aspirin is potentially more toxic than other NSAIDs because it irreversibly inactivates cyclooxygenase by acetylation,
whereas other NSAIDs reversibly inhibit cyclooxygenase.[162] However, phenylbutazone is the drug most 896
commonly reported to cause toxicity in horses, perhaps because of its widespread use by veterinarians and 897
horse owners. Phenylbutazone toxicity in horses is characterized by mucosal ulceration throughout the gastrointestinal tract, oral ulceration, renal papillary necrosis, vasculopathy, thrombosis, and protein-losing enteropathy with hypoalbuminemia.[164–166] This discussion focuses on the toxic effects of NSAIDs on the large intestine but necessarily includes elements of upper gastrointestinal and renal disease.

Horses with large intestinal disease resulting from NSAID toxicity generally are receiving inappropriately large doses. The dosage regimen recommended for phenylbutazone (4.4 mg/kg twice in 1 day and then 2.2 mg/kg twice daily) is considered to be safe. Experimental studies in horses, however, have shown toxicity to occur when greater than the recommended dosage (6.6 mg/kg/day) is administered for several days.[164,165] In most reported cases of phenylbutazone toxicosis horses were receiving higher than recommended dosages.[166,168,169] Regardless, administration of phenylbutazone at the recommended dosage has been reported to cause a significant decrease in plasma protein concentration and gastrointestinal disease.[165,170] Moreover, signs of NSAID toxicity have been reported in normovolemic horses treated with appropriate doses of phenylbutazone.[170,171] Dehydration, sepsis, and endotoxemia exacerbate the renal and gastrointestinal toxicity of NSAIDs.[162] Clearly, the margin of safety is narrow for phenylbutazone and probably for other NSAIDs used in horses as well.

Gastrointestinal disease induced by NSAIDs is manifested by mucosal ulceration, inflammation, bleeding, and protein-losing enteropathy.[164,165,168,170] In addition to direct effects on the mucosal barrier, NSAID administration has been shown to cause an acute relapse of preexisting colonic inflammatory disease and worsen colonic inflammation in human beings.[164,165,170] Whether this occurs in horses is not clear. The mechanism by which NSAIDs induce mucosal damage is probably multifactorial. Direct irritation may play a role in oral and gastric irritation and ulceration; however, parenteral administration of NSAIDs produces oral and gastric ulceration as well. Inhibition of prostaglandin synthesis by inhibition of cyclooxygenase 1 (the constitutive COX) and cyclooxygenase 2 (the inducible COX) appears to be the most important mechanism of mucosal injury. Prostaglandins, particularly PGE_2 and PGI_2, are critical for mucosal health.

[172,173] PGE_2 has been shown to increase mucosal blood flow; increase secretion of mucus, water, and bicarbonate; increase mucosal cell turnover rate and migration; stimulate adenyl cyclase activity; and exert other protective effects in the gastric mucosa of several species.[162,172,173] Perhaps most importantly, PGE_2 and PGI_2 have a role in maintaining epithelial tight junction integrity, which is indispensable for mucosal barrier function and repair after mucosal injury.[172]

In spite of the overwhelming amount of information about the role of prostaglandins in maintaining the mucosal barrier in other species and clear clinical and experimental evidence that NSAIDs injure the equine colonic mucosa, the role of prostaglandins in mucosal protection in the equine colon is not yet well defined. Inhibition of COX-1 and COX-2 in equine colonic mucosa with flunixin meglumine resulted in reduced electric resistance of the mucosa and increased permeability to macromolecules in vitro (A.T. Blikslager and S.L. Jones, 2002), suggesting that flunixin treatment disrupts the epithelial tight junctions in the equine colon. Mucosal changes were correlated with a profound inhibition of PGE_2 and PGI_2 concentrations in the treated tissues. In other studies, administration of a PGE_2 analog prevented the gastrointestinal manifestations of phenylbutazone toxicosis in ponies.[165]

Recent development of NSAIDs specific for COX-2 have greatly reduced the frequency and severity of gastrointestinal side effects in human beings taking NSAIDs for chronic musculoskeletal conditions.[174] Thus COX-2–specific NSAIDs hold promise for use in horses to treat arthritis and reduce the incidence of toxicity. For example, the COX-2–specific inhibitor etodolac was less harmful to equine colonic mucosa than flunixin meglumine in vitro (A.T. Blikslager and S.L. Jones, 2002). Moreover, etodolac was significantly more permissive than flunixin for recovery of the mucosa in equine ischemic-injured intestinal tissues, and in fact, recovery was no different than control tissues.[175] However, their use is at present limited because the specificity of the so-called COX-2– selective inhibitors and their efficacy as analgesics have not been demonstrated in the horse.

NSAID-induced mucosal injury is associated with a significant inflammatory response to microbial products exposed to the lamina propria.[176] This inflammation exacerbates mucosal dysfunction and injury associated with NSAID toxicity. For example, depletion of neutrophils or blockade of neutrophil influx into gastrointestinal tissues or inhibition of neutrophil activation and release of toxic products prevents many of the pathophysiologic effects of NSAID toxicity in the gastrointestinal tract.[177–180] The inflammatory response alone may result in moderate to severe gastrointestinal ulceration, mural vascular thrombosis and edema, fluid secretion, protein-losing enteropathy, and mucosal hemorrhage.

13.13.3.2.2 Clinical Signs and Diagnosis

NSAID colitis manifests as two clinical syndromes: right dorsal colitis (RDC) and generalized NSAID toxicity. RDC is an ulcerative disorder isolated to the right dorsal segment of the large intestine.[167,168,171] The most prominent clinical signs of RDC are anorexia, lethargy, and colic. Anorexia, depression, diarrhea, 897
fever, and signs of endotoxemia also may be features. If the RDC is chronic, weight loss, intermittent colic, 898
lethargy, anorexia, and ventral edema are common clinical signs, along with soft and unformed feces. Severe ulceration of the right dorsal colonic mucosa results in protein-losing enteropathy and significant hypoproteinemia attributable mainly to hypoalbuminemia. Hypoproteinemia may be severe enough to cause peripheral (usually ventral) edema. In some cases, one may note dehydration, electrolyte abnormalities,

neutropenia or anemia, azotemia, and biochemical abnormalities if the ulceration and diarrhea are severe or if systemic inflammation is present.

Clinical signs of generalized NSAID toxicity may vary from mild diarrhea with no systemic signs to severe dehydrating diarrhea with anorexia, fever, depression, peripheral edema, oral ulceration, and colic.[165,166,169] Clinical signs of systemic inflammation caused by endotoxemia may occur, manifested as poor peripheral perfusion, tachycardia, tachypnea, weakness, trembling, and cyanotic or hyperemic oral mucous membranes. Hematuria or oliguria may be present if renal involvement is present. Complications associated with other forms of severe enterocolitis, such as laminitis, thrombophlebitis, and severe weight loss, may occur.

Hematologic abnormalities of generalized NSAID toxicity are nonspecific and include neutropenia with a left shift or leukocytosis and hemoconcentration. Serum biochemical analysis is characterized by profound hypoproteinemia, hyponatremia, and metabolic acidosis.[169,170] Hypocalcemia, hypokalemia, hypochloremia, and elevated hepatocellular enzyme activities also may occur. Hypoproteinemia may occur without signs of diarrhea. Azotemia may be prerenal from dehydration but frequently is caused by renal failure resulting from a combination of hemodynamic and toxic renal injury. Urinalysis frequently reveals hematuria, proteinuria, cylindruria, and isosthenuria. Fecal occult blood is frequently detectable.

Diagnosis of either form of NSAID colitis is often presumptive, with a history of overdose of NSAIDs being strong evidence of NSAID toxicity. But as discussed earlier, toxicity may occur with dosage regimens that are not considered inappropriate, particularly if the horse experiences a concurrent period of dehydration. One can use ultrasonographic examination of the right dorsal colon to confirm a diagnosis of RDC, but the sensitivity of this method is questionable. Ultrasonography (3.5- to 5-MHz transducer at the right twelfth to fifteenth intercostal spaces below the margin of the lung axial to the liver) may reveal a thickened right dorsal colon (>0.5 cm) and evidence of colonic edema in horses with RDC.[181] However, the sensitivity of this method of diagnosis is questionable. One can use nuclear scintigraphy of horses after infusion with technetium 99–labeled white blood cells to document inflammation of the right dorsal colon.[182] Diagnosis of RDC may require one to perform laparotomy or laparoscopic examination of the right dorsal colon. One must rule out other causes of enterocolitis, such as salmonellosis, Potomac horse fever, clostridiosis, and antibiotic-associated diarrhea.

13.13.3.3 CANTHARIDIN TOXICITY

13.13.3.3.1 Pathogenesis

Cantharidin is the toxic principle found in beetles of the genus *Epicauta,* commonly known as blister beetles.[183–185] Ingestion of the beetles in contaminated alfalfa hay causes release of the toxin from the tissues of the beetle and absorption through the gastrointestinal tract. Transcutaneous absorption may occur but appears to be rare in horses.[184] Blister beetles feed on the flowers of alfalfa and may be incorporated into processed alfalfa hay if the hay is cut and processed simultaneously, as by crimping.[183–185] The beetles often swarm, and one may find large numbers of beetles in small portions of hay. The lethal dose of cantharidin is less than 1 mg/kg, but the concentration of cantharidin varies from species to species of blister beetles and between sexes.[183,184] As many as 100 to as few as 6 to 8 beetles may be lethal. Usually, only one or a few horses fed contaminated hay ingest beetles because the beetles are concentrated in a small portion of the hay. However, outbreaks involving many horses on a farm have occurred. Most cases occur

in Texas and Oklahoma, but horses in other states may be affected as well, especially if hay is imported from states where blister beetles are common. Peak incidence is in late summer and fall.[186] The fatality rate may be 50% or greater,[183,187] but if the patient survives several days, recovery is probable.

Cantharidin is absorbed from the gastrointestinal tract and excreted via the kidney. Cantharidin is a potent irritant, causing acantholysis and vesicle formation when applied topically.[183,185,187] The chemical is thought to disrupt oxidative metabolism in the mitochondria, causing mitochondrial swelling, plasma membrane damage, and changes in membrane permeability.[183] The mucosa of the gastrointestinal tract is affected most commonly in horses because they ingest the toxin. Cell swelling and necrosis occur, resulting in mucosal ulceration. Oral, esophageal, gastric, and small and large intestinal ulceration have been observed in natural and experimental canthariasis.[183,185,187] Severe fibrinous to pseudomembranous inflammation and submucosal edema of the intestine also have been reported. Diarrhea probably results from the severe ulceration and inflammation of the large intestine, causing increased secretion of water, electrolytes, and protein and decreased absorption of fluid. Large volumes of fluid and protein are lost in the 898
gastrointestinal tract, causing hemoconcentration and profound hypoalbuminemia in some cases.[183,184,187] 899

Cystitis and myocarditis occur in natural and experimentally produced cases of cantharidin toxicity.[183,185,187] Cystitis occurs because renal excretion of cantharidin results in high concentrations in urine. Occasionally, hemorrhagic cystitis may occur, with hematuria or frank hemorrhage into the bladder.[183] The cause of the myocarditis and myocardial necrosis is unknown but also may be a direct effect of the toxin on the myocardium. Elevated plasma creatine kinase activity often occurs and has been postulated to arise from the damaged myocardium.[183,184] Horses have a characteristically stiff gait, but histopathologic evidence of skeletal muscle injury that explains the elevated plasma creatine kinase activity has not been observed.[184] The kidneys are often pale, swollen, and moist, with occasional infarcts.[185]

Hypocalcemia and hypomagnesemia are biochemical features of cantharidin toxicity in horses that have not been explained.[183,184,187] Hypocalcemia may occur from hypoalbuminemia, but the ionized calcium concentration often is decreased along with the total calcium concentration, indicating that hypoalbuminemia is not responsible for the hypocalcemia.[184] In addition, clinical signs of hypocalcemia, such as synchronous diaphragmatic flutter, are often associated with hypocalcemia from cantharidin toxicity. Hypocalcemia associated with hypoalbuminemia alone does not produce clinical signs.

13.13.3.3.2 Clinical Signs and Diagnosis

Cantharidin toxicity can cause a range of clinical signs from mild depression and abdominal discomfort to fulminant signs of toxemia and rapid death, depending on the ingested dose of toxin. Most commonly, clinical signs include depression, sweating, irritability, abdominal pain, elevated heart and respiratory rates, fever, polyuria, polydypsia, and profuse diarrhea.[183,184,187] Blood is rarely visible in the feces. Affected horses frequently posture to urinate; indeed, stranguria and pollakiuria are characteristic of cantharidin toxicity.[183] Signs of hypocalcemia include synchronous diaphragmatic flutter and tremors. A stiff and stilted gait may be evident. One may note neurologic signs such as head pressing, swaying, and disorientation.[187] Signs of systemic inflammation from endotoxemia may be apparent in severe cases. Some horses develop severe depression and toxemia and may die within hours after ingestion of cantharidin without developing diarrhea.[183,187]

Hematologic abnormalities include hemoconcentration and neutrophilic leukocytosis. Occasionally, neutropenia and leukopenia may accompany endotoxemia. Serum biochemical analysis usually reveals elevated creatine kinase activity, hypocalcemia, and hypoalbuminemia.[183,184] Biochemical abnormalities include hypocalcemia (ionized and total calcium concentrations), hypomagnesemia, and azotemia.[183,184,187] Urine specific gravity is characteristically in the hyposthenuric range.[183,184] Microscopic hematuria and mild proteinuria may be evident. Fecal occult blood is often present, but hematochezia is unusual.

One can make a tentative diagnosis based on clinical signs and the finding of blister beetles in the hay. Determining the species of the insects may be necessary to estimate the amount of cantharidin ingested. All species of *Epicauta* contain cantharidin, but some have small amounts. Definitive diagnosis requires the measurement of the cantharidin concentration in gastric or intestinal contents and urine.[183,186] Measurement of cantharidin concentration in the beetles is often done but is not necessary.

13.13.3.4 ARSENIC TOXICOSIS

13.13.3.4.1 Pathogenesis

Arsenic toxicosis is an unusual cause of diarrhea in horses, resulting from ingestion of arsenic-containing herbicides, insecticides, and other pest control products contaminating water or roughage used as a food source.[188] The toxicity of arsenic depends on the valence of the element.[188,189] Arsenate may be reduced to arsenite in mammalian systems, and arsenite is thought to be more toxic than arsenate and less rapidly excreted in urine. Arsenate and arsenite uncouple oxidative phosphorylation, leading to breakdown of energy metabolism in the cells of many tissues.[189] Widespread cellular injury and death occur rapidly during acute arsenic toxicosis. Multiorgan failure usually results. In fact, cardiomyopathy and pulmonary disease are common causes of death in human beings.[190] Damage to the large intestine is probably caused in part by direct cellular toxicity and corrosion by the compound. However, vasculitis is a hallmark of the disease in human beings and horses and is thought to be the most important mechanism of large intestinal disease in human beings.[181,191] Acute hemorrhagic colitis is a feature of arsenic toxicosis, with severe mural edema and mucosal ulceration.[188] Profuse, hemorrhagic diarrhea and abdominal pain result. Chronic arsenic toxicity can occur but appears to be rare in horses.

13.13.3.4.2 Clinical Signs and Diagnosis

Acute depression, weakness, abdominal pain, hemorrhagic diarrhea, and shock are characteristic of acute arsenic toxicosis in horses. Death may occur before diarrhea is evident. Initial clinical signs may be difficult to distinguish from other peracute forms of colitis and are related to endotoxic shock, metabolic disturbances, and dehydration. Later, cardiac arrhythmias, pulmonary edema, acute renal failure, and
neurologic deficits (ataxia and stupor) may develop.[188] One may observe anuria or polyuria. Hemolytic 899
anemia caused by preferential binding of arsenic compounds to red blood cells is a feature of arsenic 900
poisoning in human beings. Hematologic abnormalities may be apparent after the peracute stages from injury to bone marrow cells and ongoing hemolysis. Leukopenia and thrombocytopenia have been described in human patients.[190] Serum biochemical analysis may reveal azotemia, hepatocellular enzyme activities higher than generally attributed to endotoxemia, and elevated creatine kinase activity.[188] Urine specific gravity may be in the isosthenuric range, with hematuria, cylindruria, and proteinuria evident by urinalysis.

Diagnosis may be possible by measuring blood and urine arsenic concentration, but these tests may not be diagnostic. Postmortem diagnosis is by measuring the arsenic concentration in liver and kidney samples.[188] History of exposure and clinical signs remain the primary means of diagnosis.

13.13.4 Miscellaneous Disorders of the Large Intestine

Other disorders associated with diarrhea in adult horses include anaphylaxis, carbohydrate overload, and sand enteropathy. Careful evaluation of history, environment, and management will assist the clinician in arriving at an accurate diagnosis.

13.13.4.1 INTESTINAL ANAPHYLAXIS

13.13.4.1.1 Pathogenesis

Severe intestinal anaphylaxis is a syndrome in horses characterized by peracute, rapidly fatal colitis.[192] The severe syndrome is clinically and pathologically similar to other known causes of peracute colitis, such as salmonellosis, clostridiosis, and antibiotic-associated diarrhea. Some cases are less severe and manifest as mild to moderate diarrhea or colic. An IgE-mediated type I hypersensitivity or an IgE-independent anaphylactoid reaction can produce the syndrome of intestinal anaphylaxis.[193,194] Local gastrointestinal exposure to a food, environmental contaminant, drug, or other allergen usually induces intestinal anaphylaxis,[193,195] but anaphylaxis also may occur with systemic exposure to an allergen.[196–199] Massive mast cell degranulation, secretion of inflammatory mediators, and activation of enteric neural reflexes in the intestine causes profound alterations in blood flow, increased vascular permeability and interstitial edema, recruitment of neutrophils, altered motility, mucosal injury, absorption of microbial products, and mucosal hypersecretion.[200–204] Systemic signs may be caused by the anaphylactic reaction or may be associated with systemic inflammation triggered by microbial products (endotoxin) absorbed through the injured and hyperpermeable mucosa.

Intestinal anaphylaxis in horses may be a peracute, fulminant enterocolitis with endotoxemia that may be fatal.[192,205] This form is characterized by severe intramural edema and hemorrhagic inflammation of the large intestine, often producing submucosal thickening on the order of many centimeters. Vascular thrombosis may be widespread with mucosal and serosal petechia and ecchymoses. Less severe forms of intestinal anaphylaxis may manifest as patchy areas of intestinal edema and congestion.[196] Diarrhea results from intestinal inflammation initiated by the type I hypersensitivity response. Many of the mediators of type I hypersensitivity, such as histamine and 5-hydroxytryptamine, have well-documented stimulatory effects on mucosal secretory activity, vascular and epithelial permeability, and motility[200–202] in the intestine. Systemic inflammation from endotoxemia may be overwhelming once the mucosal barrier breaks down. Infarction of intestinal segments and other organs may occur from intravascular coagulation. Ileus, abdominal distention, and moderate to severe abdominal pain may result from motility disturbances and infarction of the large intestine.

13.13.4.1.2 Clinical Signs and Diagnosis

The clinical signs are similar to those described for other forms of peracute colitis. However, the severity may vary, manifesting as colic or moderate diarrhea. Characteristically, severe shock, signs of systemic inflammation from endotoxemia, and severe metabolic disturbances are observable.[192,205] Heart and respiratory rates may be elevated greatly, with other signs of cardiovascular collapse such as weak and thready peripheral pulses and peripheral vasoconstriction. However, peripheral vasodilation may occur later in the course of disease. Dark red, muddy, or cyanotic mucous membranes with a prolonged capillary refill time signify sepsis. Borborygmi are usually absent, and abdominal tympany may be heard on percussion, following ileus. Moderate to severe colic may accompany ileus. Severe diarrhea may occur, but death may occur before diarrhea is evident. Multiorgan failure from disseminated intravascular coagulation is not unusual. Rapid onset of weakness, staggering, and trembling commonly precedes death. The syndrome may cause death in 4 to 24 hours.

Hematologic abnormalities include severe neutropenia and leukopenia, thrombocytopenia, and hemoconcentration.[192] Serum biochemical alterations include hyponatremia, hypokalemia, hypocalcemia, and severe metabolic acidosis. Blood urea nitrogen and creatinine may be elevated from prerenal or renal azotemia. If acute renal failure accompanies the colitis, hyperkalemia may result. Hepatocellular enzyme activity may be elevated in the serum from endotoxemia. Severe coagulopathies are common, resulting in 900
prolonged coagulation times, elevated fibrinogen, decreased antithrombin III activity, and elevated plasma 901
concentration of fibrin degradation products. Analysis of peritoneal fluid may be valuable because infarction of the large intestine is not unusual. Protein concentration and the white blood cell count may be elevated. Red blood cell counts are less likely to be elevated, because infarction and not strangulation of the intestine occurs.

Diagnosis is based on clinical signs, postmortem findings, and exclusion of other causes. Cultures and toxicologic analysis of fecal samples and gastrointestinal tissues fail to demonstrate a clear cause. Other diagnostic tests are also inconclusive. If an antigen is suspected as the trigger of the anaphylaxis, a Prausnitz-Küstner passive cutaneous anaphylaxis sensitization test can confirm the presence of antigen-specific IgE in the patient serum.[196]

13.13.4.2 CARBOHYDRATE OVERLOAD

13.13.4.2.1 Pathogenesis

Overeating of soluble carbohydrates, especially so-called hot grains such as corn, overwhelms the digestive capability of the small intestine, resulting in a high percentage of the soluble carbohydrates entering the large intestine. The amount of soluble carbohydrates that produce diarrhea varies according to the previous dietary history of the individual. Horses fed diets higher in soluble carbohydrates are more resistant to the deleterious effects of carbohydrate overload. Gradual accommodation to a diet high in carbohydrates can be accomplished over several weeks. However, horses fed an unusually large amount of grains or other form of soluble carbohydrates often develop diarrhea and may, depending on the amount ingested, develop severe colitis, systemic inflammation from endotoxemia, metabolic acidosis, and laminitis.[206–209]

The pathogenesis of colitis from carbohydrate overload is caused primarily by the toxic effects on the microbial flora in the large intestine.[207] A sudden delivery of soluble carbohydrates to the large intestine causes rapid fermentation by gram-positive lactic acid–producing bacteria and a sudden increase in organic acid production. The cecal pH rapidly decreases, and the lactic acid concentration rapidly increases. Rapid organic acid production overwhelms the buffering capacity of the large intestine not only by directly depleting the buffers found in the contents but also by reducing the efficiency of buffer secretion. Bicarbonate secretion is linked to absorption of volatile fatty acids, which are produced in low amounts by fermentation of soluble carbohydrates. The contents of the large intestine become profoundly acidic, resulting in unfavorable conditions for the microbial flora. Lactic acid–producing bacteria flourish, while the gram-negative bacteria, especially the Enterobacteriaceae, are killed in large numbers by the acids. Large quantities of endotoxin are released from the dying bacteria.[208]

The osmotic load from the lactic acid produced in the large intestine is an important factor in the development of diarrhea because organic acids such as lactic acid are absorbed poorly. Mild cases of carbohydrate overload may result purely from osmotic diarrhea. In more severe cases, the acidic contents of the large intestine are toxic to the mucosa, causing necrosis of the mucosal tissues, similar to that occurring in ruminal acidosis. Mucosal ulceration allows absorption of large quantities of endotoxin and lactic acid produced by the massive die-off of acid-intolerant microbes and fermentation of soluble carbohydrates, normally poorly absorbed by intact mucosa.[209] Systemic inflammation from endotoxemia may be overwhelming, and profound metabolic acidosis may occur. Secretory diarrhea caused by the direct effects of acid luminal contents on the mucosa, as well as the effects of inflammatory mediators on enterocyte secretion, worsens the acidosis and dehydration. Systemic inflammation from endotoxemia, along with intestinal inflammation, adversely affects intestinal motility, and ileus develops. Ileus and gas production from fermentation of the carbohydrates may cause severe distention of the large intestine and signs of abdominal pain. Laminitis is a frequent complication of endotoxemia and lactic acidosis. In fact, carbohydrate overload is used to induce laminitis as an experimental model because of the consistency of the laminitis produced.[207–209]

13.13.4.2.2

Clinical Signs and Diagnosis

Clinical signs of colitis from carbohydrate overload can vary according to the amount of carbohydrates ingested and accommodation of the flora to a high-carbohydrate diet. Mild cases may result in a transient osmotic diarrhea with no systemic effects. More severe cases are characterized by signs similar to those described for other forms of colitis, including abdominal pain, moderate to severe diarrhea, and dehydration. Signs of endotoxemia and sepsis are frequently present in severe cases. Elevated heart and respiratory rates are common, with peripheral vasoconstriction early in the disease, followed by peripheral vasodilation as the disease progresses. Depression may be profound from metabolic acidosis and endotoxemia. Abdominal auscultation and percussion may reveal ileus and intestinal tympany. Nasogastric intubation may yield significant gastric acidic reflux. One may note particles of grain in the gastric reflux and the feces, if grain overload is the source of the carbohydrate overload. Laminitis may complicate mild and severe cases of carbohydrate overload, especially if the animal has had previous bouts of laminitis.

Hematologic abnormalities include neutropenia and leukopenia. Severe dehydration may result in profound hemoconcentration. Protein loss later in the course of disease may result in hypoproteinemia. Serum 901
biochemical abnormalities include azotemia, elevated hepatocellular enzyme activity, hyponatremia, and 902
hypokalemia. Severe hypocalcemia and metabolic acidosis are characteristic of the disease. Serum lactate

concentrations are elevated in the absence of evidence of intestinal strangulation or infarction. Peritoneal fluid analysis often reveals no abnormalities.

13.13.4.3 SAND ENTEROPATHY

Sand enteropathy is described in more detail under the heading of obstructive diseases, because acute obstruction is often associated with abnormally large amounts of sand in the large intestine.[210] However, chronic sand-induced diarrhea is a distinct syndrome that can occur at any age from abnormal accumulation of sand in the large intestine.[211,212] Chronic diarrhea and signs of colic may occur without obstruction. The pathogenesis of sand accumulation in individual horses, other than simple ingestion of large quantities, is unclear. Presumably the sand causes irritation and may disrupt motility, leading to diarrhea. The diarrhea is usually not severe and dehydrating and may be intermittent. Weight loss is characteristic and can be severe in some cases. Complications may occur such as peritonitis and acute obstruction.[211]

Diagnosis usually is based on finding abnormal amounts of sand in the feces. Because sand-induced chronic diarrhea is associated primarily with sand accumulation in the ventral colon, auscultation of the ventral abdomen immediately behind the xiphoid process may reveal characteristic sand sounds.[213] This technique is only sensitive if peristalsis is present. Ultrasonography also may be useful to identify sand in the ventral colon but is not useful to quantitate the amount of sand. Occasionally, radiography may be required to detect sand in the colon.[211]

13.13.5 Principles of Therapy for Acute Diarrhea

The principles of therapy of acute diarrhea from colitis are similar regardless of the cause and include replacement of fluid and electrolyte losses, control of colonic inflammation and reduction of fluid secretion, promotion of mucosal repair, control of endotoxemia and sepsis, and reestablishment of normal flora. This section focuses on a review the principles of therapy with references to specific therapies for particular causes as they arise.

13.13.5.1 FLUID REPLACEMENT AND CIRCULATORY SUPPORT

Replacement of fluid and electrolyte losses is of primary concern in treating horses with salmonellosis. Depending on the severity of the disease, fluid losses may be minimal or massive. One can administer fluid and electrolytes orally or intravenously. Some horses with mild to moderate diarrhea may maintain hydration and electrolyte balance by consuming water and electrolytes voluntarily. Freshwater and water containing electrolytes should be available in all cases. In many instances, periodic nasogastric intubation and administration of water and electrolytes via the tube may be sufficient to maintain hydration.[214] In more severe cases, one can maintain indwelling nasogastric tubes and can administer up to 4 to 8 L of fluid by the tube every 20 to 30 minutes, if ileus is not evident. However, intravenous administration of fluids is preferred in most cases, requiring significant quantities of fluid to replace and maintain hydration and electrolyte balance.[215] For patients with severe diarrhea to require large volumes (50 to 100 L/day) of intravenous fluids to maintain hydration is not unusual. Frequent monitoring of packed cell volume, serum electrolyte concentration, venous blood gases or total serum carbon dioxide, blood urea nitrogen and creatinine, urine protein and cytologic findings, and body weight is important to monitor hydration, electrolyte and acid-base balance, and renal function.

Isotonic sodium chloride or lactated Ringer's solution frequently is used to restore and maintain fluid and electrolyte balance. One can add potassium chloride to the fluids and administer it at a rate up to 0.5 to 1.0 mEq/kg/hr. Generally, a rate of less than 0.5 mEq/kg/hr is used. Hypertonic NaCl solutions (1 to 2 L of 3% to 5% NaCl) have been used in horses that are severely hyponatremic ($<$120 mEq/dl). One should not administer hypertonic solutions to severely dehydrated horses, but such solutions have been used clinically without complication and with considerable beneficial effect in patients with endotoxemia. The beneficial effects of hypertonic NaCl are short-lived (30 to 60 minutes). One should administer isotonic solutions concurrently or immediately following administration of hypertonic NaCl solutions. Isotonic (1.3%) or hypertonic (5.0%) sodium bicarbonate solutions are used to correct metabolic acidosis. Prolonged administration of sodium-containing fluids may promote diuresis and renal water loss or accumulation of peripheral edema and should be used conservatively when one notes a free water loss. Administration of isotonic dextrose (5%) or 2.5% dextrose/0.45% NaCl solutions may be beneficial when free water loss (sodium excess) is evident.

Many horses with acute colitis are concurrently hypoproteinemic because of gastrointestinal losses and are absorbing bacterial products that induce a systemic inflammatory response. Thus plasma oncotic pressures are abnormally low in the face of increased vascular permeability. Interstitial edema formation is a clinical problem in these patients and contributes to organ dysfunction. Crystalloid fluids, although critical for 902
replacing water and electrolyte losses from diarrhea, actually may contribute to a drop in plasma oncotic 903
pressure because of hemodilution.[216,217] Administration of colloid solutions are important for volume expansion and to maintain plasma oncotic pressures, which improve tissue perfusion and oxygenation and organ function in hypovolemic, hypotensive, and hypoproteinemic patients with or without systemic inflammatory response syndrome.[218] Colloids are more effective than crystalloid fluids at expanding plasma volume and thus require smaller volumes. Moreover, the effect of colloid volume expansion is longer lasting than crystalloid fluid volume expansion, because colloids are retained in the vasculature better.[217,218] Natural colloids, such as plasma and purified albumin are used commonly. In addition to its beneficial colloidal properties, plasma harvested from donor horses immunized with rough mutants of *Escherichia coli* (J5) or *Salmonella typhimurium* may have other benefits for treatment of endotoxemia from gastrointestinal disease.[219,220] The horse may require large volumes (6 to 8 L/day) to increase and maintain plasma protein concentration significantly. Synthetic colloids such as dextrans, starches, or polymerized hemoglobin are also available for use in the horse. Hetastarch (5 to 10 ml/kg of a 6% solution) increases colloidal oncotic pressures for up to 24 hours in hypoproteinemic horses and has beneficial effects on cardiac output and other cardiorespiratory parameters, vascular permeability, interstitial fluid content, and tissue perfusion in models of hypoproteinemia and systemic inflammatory response syndrome. When one administers synthetic or even natural colloids, monitoring plasma oncotic pressure may be more relevant than monitoring plasma protein concentrations as a means of assessing the need for plasma or other colloid administration.[216] Hetastarch may prolong bleeding times by altering von Willebrand's factor function; thus one should use this synthetic colloid cautiously in horses with suspected coagulopathies, active hemorrhage, or other bleeding problems.[217]

13.13.5.2 INFLAMMATION

Control of colonic inflammation and secretion is a difficult and poorly studied aspect of equine acute colitis. The role of inflammation and mediators such as prostaglandins as causes of fluid loss is well known for *Salmonella* and *Clostridium* infections. COX inhibitors (NSAIDs) have antisecretory effects in the equine colon and in models of salmonellosis that appear to extend to clinical management of salmonellosis.[16,36,221–223] Indeed, NSAIDs commonly are administered to horses with salmonellosis. However, prostaglandins such

as PGE_2 and PGI_2 are also cytoprotective to gastrointestinal mucosa and critical for mucosal repair.[172] The doses of NSAIDs used pharmacologically to inhibit colonic inflammation and secretion in fact may be detrimental to the mucosa if not used judiciously. NSAIDs have been shown to exacerbate colonic inflammation in human beings with inflammatory colitis, impede mucosal healing in several models of mucosal injury, and have well-documented detrimental effects on colonic mucosa in horses.[164,172,224] In addition to toxicity to the colonic mucosa, gastric ulceration is not unusual in horses with enterocolitis and may be related to treatment with NSAIDs.

In addition to NSAIDs, other drugs occasionally are used as antiinflammatory or antisecretory therapy. Metronidazole has beneficial effects in experimental models of gastrointestinal inflammation, including NSAID toxicity[176] and may be useful for treating horses with colitis, but evidence supporting its use is lacking. Bismuth subsalicylate solutions administered orally often are used to decrease inflammation and secretion in the colon. In adult horses the volume of solution necessary to be beneficial is large (3 to 4 L every 4 to 6 hours). Often the solution is administered twice daily instead of 4 to 6 times daily. If one does not achieve a beneficial effect within 3 to 4 days of treatment, one should discontinue administration of bismuth subsalicylate solution. One can administer the treatment more frequently in foals, and clinical improvement occurs more often in foals than in adult horses.

In light of the role of reactive oxygen metabolites in colonic inflammation, free radical scavengers have been advocated to reduce the effects of these molecules. Sulfasalazine metabolites have been shown to reduce reactive oxygen metabolite–induced colonic inflammation in other species,[176] and sulfasalazine has been used to treat chronic inflammatory disease in horses but has not been used to treat acute colitis. The only free radical scavenger used commonly in horses with colitis is dimethyl sulfoxide, which at a dosage of 0.1 to 1.0 g/kg intravenously every 12 to 24 hours in a 10% solution has been used in clinical cases of colitis, but evidence of efficacy has not been established.

Systemic inflammatory response syndrome associated with endotoxemia frequently occurs in patients with salmonellosis. The principles of therapy for endotoxemia are covered in detail elsewhere in this chapter. Oral administration of activated charcoal and mineral oil is used commonly to reduce absorption of endotoxin in horses with colitis. Low doses of NSAIDs (such as flunixi n meglumine at 0.1 to 0.25 mg/kg intravenously every 6 to 8 hours) inhibit eicosanoid synthesis induced by endotoxin. In addition, administration of NSAIDs prevents laminitis from endotoxemia, a devastating complication of salmonellosis. One must remember that prostaglandins are important for mucosal healing and may worsen mucosal injury in colitis. Although the 903
benefits of low doses of NSAIDs administered to horses with systemic inflammatory response syndrome are 904
believed to outweigh the risks of worsening gastrointestinal damage, judicious use is recommended.

13.13.5.3 MUCOSAL REPAIR AND PROTECTION

Sucralfate (20 mg/kg orally every 6 hours) has been advocated to aid in healing the colonic mucosa, but the efficacy in the large intestine is questionable.[94] Misoprostol (2 μg/kg orally 3 to 4 times daily) and other synthetic PGE analogs have been shown in several species including horses to enhance mucosal healing in the intestine and promote recovery in experimental models of colitis.[225] Misoprostol may be particularly useful for treating NSAID toxicity, the generalized form or RDC. However, the efficacy of misoprostil for hastening mucosal healing is clinically unproven in equine colitis. The primary drawbacks of prostaglandin analogs such as misoprostol are the side effects of the drug, including abdominal cramping, diarrhea, sweating, and abortion in pregnant mares.

One can add psyllium mucilloid to the diet (5 tablespoons once or twice daily) to increase the production of SCFAs in the colon. Amylase-resistant fermentable fiber such as psyllium is hydrolyzed by colonic bacteria to SCFAs such as butyrate, which represent a major energy source for colonocytes. Butyrate and other SCFAs hasten epithelial maturation and stimulate salt (and thus fluid) absorption in the colon, improve the clinical course of ulcerative colitis, and hasten colon healing.[226] Psyllium is itself a source of butyrate in the colon and also promotes the movement of amylase sensitive carbohydrates into the distal colon, which then are fermented to SCFAs. Thus psyllium is thought to be clinically useful for promoting mucosal healing in colitis.

13.13.5.4 PAIN CONTROL

Many horses with salmonellosis or other forms of colitis have mild to severe signs of abdominal pain from gas and fluid distention of the colon, colonic ischemia, or infarction. One can accomplish analgesia with NSAIDs such as flunixin, but the potential for worsening mucosal injury or nephrotoxicity may prevent the use of analgesic doses, especially in horses with suspected NSAID toxicity. Newer NSAIDs that specifically target COX-2 (the inducible COX) but have little activity against COX-1 (the constitutive COX) may be useful analgesics that spare the gastrointestinal mucosa. For example, etodolac (10 to 15 mg/kg intravenously or orally once daily) has analgesic properties in horses and may spare the intestinal mucosa from the detrimental effects associated with nonselective COX inhibitors (A.T. Blikslager, personal communication, 2002). However, the specificity for COX-2 in horses is unproven. Thus avoiding the use of any NSAIDs in horses with RDC or other forms of NSAID toxicity is advisable.

Xylazine or detomidine may provide temporary relief of pain. Butorphanol is a useful analgesic that one can administer intramuscularly (0.1 mg/kg every 6 hours) or as a continuous infusion. An infusion of 13.2 μg/kg/hr in isotonic crystalloid fluid such as lactated Ringer's solution has been suggested.[227] Continuous lidocaine infusions (1.3 mg/kg intravenous loading dose administered slowly over 5 minutes and followed by 3 mg/kg/hr infusion in isotonic crystalloid fluids) can provide profound visceral analgesia and may have added prokinetic benefits if ileus is present.

13.13.5.5 ANTIBIOTICS

13.13.5.5.1 Neutropenia

Broad-spectrum antibiotic treatment often is recommended in neutropenic horses or horses with signs of septicemia. Neutropenia is associated with an increased risk of septicemia and septic complications such as septic phlebitis and infection of surgical site.[1] Septicemia is a potentially life-threatening complication of enterocolitis and may be caused directly by *Salmonella, Clostridium,* other invasive enteric bacteria, or indirectly by toxic injury to the colonic mucosa that breaks down the barrier to luminal microbes. Neutropenia possibly may weaken host defenses enough to render horses susceptible to organisms that breach the mucosal barrier. Although most attempts to culture bacteria from the blood of adult horses with colitis fail to isolate organisms, no detailed studies have been undertaken to determine the prevalence of bacteremia or septicemia in these patients. Disseminated aspergillosis has been reported in horses as a complication of acute colitis, demonstrating the potential for systemic infections with rarely pathogenic organisms stemming from colonic mucosal injury in the face of potential immunosuppression from neutropenia.[228,229] Broad-spectrum antibiotics lessen septic complications in human patients. However, evidence supporting this principle in horses with colitis is lacking.

13.13.5.5.2
Salmonellosis

Treatment with antibiotics is controversial in horses with salmonellosis and is not thought to alter the course of the enterocolitis. Antibiotics directly targeted at the *Salmonella* are reserved for patients with the enteric fever (septicemia) form of salmonellosis, documented with positive blood cultures. Lipid-soluble antibiotics are suited ideally for *Salmonella* infections, because the bacteria persist intracellularly. Trimethoprim-sulfadiazine or other potentiated sulfa drugs, enrofloxacin, and chloramphenicol are preferred antibiotics for the enteric fever form of salmonellosis for this reason.

13.13.5.5.3
Equine Monocytic Ehrlichiosis

As with other causes of enterocolitis, the use of antibiotics for equine monocytic ehrlichiosis is controversial. Fear of inducing salmonellosis or other forms of antibiotic-induced diarrhea and the difficulty of diagnosing the disease early have caused most authors to recommend judicious use of antibiotics.[49] However, in patients with a high suspicion of *Neorickettsia risticii* infection, treatment with antibiotics often is indicated before definitive diagnosis. Lipid-soluble drugs are desirable because the organism can live within cells. Oxytetracycline (6.6 mg/kg intravenously every 24 hours), doxycycline (10 mg/kg orally every 12 hours), trimethoprim-sulfadiazine (5 mg/kg trimethoprim orally or intravenously every 8 to 12 hours and 25 mg/kg sulfadiazine every 8 to 12 hours), or erythromycin-rifampin (30 mg/kg and 5 mg/kg, respectively, orally every 12 hours) have been used effectively to treat clinical cases.[49,230–232] The tetracyclines appear to be the most effective antibiotics for treatment of Potomac horse fever. Treatment is most successful if initiated before the onset of diarrhea.[49,231]

904

905

13.13.5.5.4
Clostridiosis

If one has administered antibiotics since the onset of enterocolitis, one should discontinue administration as soon as possible. Specific treatment with metronidazole (15 to 25 mg/kg orally every 8 hours) is effective for treating clostridiosis in human beings and appears to be effective in horses.[83,233] Metronidazole resistance in clinical isolates of *Clostridium difficile* has been reported in one outbreak but appears to be rare in most human and equine cases.[234] Metronidazole-resistant isolates we re sensitive to vancomycin, which may be effective for treating clinical cases if one suspects metronidazole resistance. However, metronidazole remains the treatment of choice. Some authors describe the off-label use of *C. perfringens* type C antitoxin in cases of neonatal clostridiosis, described in more detail elsewhere.[235] Antitoxin preparations generally are not advocated for use in adult horses with clostridiosis.

13.13.5.5.5
Proliferative Enteropathy

Lawsonia intracellulare is susceptible to a variety of antibiotics in vitro, including chlortetracycline, erythromycin, penicillin, difloxacin, and ampicillin.[236] Lipid-soluble antibiotics with a large volume of distribution usually are chosen to treat proliferative enteropathy because *L. intracellulare* is an intracellular organism. Erythromycin estolate (15 to 25 mg/kg orally every 6 to 8 hours) alone or with rifampin (5 mg/kg orally every 12 hours) is the most commonly reported efficacious treatment for proliferative enteropathy. Chloramphenicol (50 mg/kg orally every 6 hours) has also been reported to be effective if erythromycin worsens the diarrhea.[115] Anecdotal reports suggest that oxytetracycline and doxycycline also may be

effective. Supportive care including maintenance of hydration and electrolyte balance and plasma or colloid administration to increase colloid oncotic pressure in hypoalbuminemic patients is also indicated. One should treat affected foals until clinical signs, hypoproteinemia, and ultrasonographic evidence of intestinal thickening resolve. The prognosis depends on the duration of the disease and the degree of fibrosis and destruction of the intestinal architecture.

13.13.5.6 ANTICOAGULATION

Hypercoagulability is a common complication of enterocolitis, associated with systemic inflammation from endotoxemia. Administration of heparin (20 to 80 IU/kg subcutaneously or intravenously every 6 to 12 hours) may prevent thrombosis in these patients, provided antithrombin III concentrations are adequate in the plasma. Concentrated sources of antithrombin III are not available for use in horses, but whole plasma may provide an important source. Treatment with heparin is thought to decrease thrombosis, especially of the jugular vein, a serious complication of salmonellosis. Low-dose aspirin treatment (15 mg/kg orally every 24 to 48 hours) along with heparin treatment may provide added benefit by irreversibly inhibiting platelet function.[237] Heparin and aspirin may have protective effects on the digital lamina.[237,238] Heparin also may enhance the phagocytic activity of the reticuloendothelial system by enhancing the efficiency of opsonins such as fibronectin and immunoglobulin, thereby stimulating phagocytosis of products of coagulation and possibly other particles, including bacteria.[239,240]

13.13.5.7 PROBIOTICS

13.13.5.7.1 Salmonellosis

Maintenance of the bacterial flora and antagonism of pathogenic bacteria such as *Salmonella* in the gastrointestinal tract are important defense mechanisms preventing colonization by pathogenic bacteria. The use of probiotic preparations containing beneficial bacteria has been shown to prevent colonization of pathogenic bacteria, including *Salmonella,* in poultry.[241] Little work has been done to investigate the efficacy of these products in preventing salmonellosis in horses, but ongoing studies may provide important information. Probiotic and other preparations designed to restore normal flora to the gastrointestinal tract, such as fecal suspensions, sour milk, and yogurt, have been used clinically to shorten the course of salmonellosis, with variable results. Therefore prevention of infection by using probiotic agents and other means is important. Exposure of susceptible horses to *Salmonella* should be avoided, but the task is difficult, especially because asymptomatic infections are common and the bacteria are ubiquitous in the environment. Prophylactic use of probiotic preparations, judicious use of antibiotics in susceptible horses, 905
control of environmental conditions such as temperature, and restricted exposure to pathogenic bacteria are 906
important for control of salmonellosis.

13.13.5.7.2 Clostridiosis

Because altered large intestinal flora appears to play an important role in the pathogenesis of equine intestinal clostridiosis or any antibiotic-associated diarrhea, probiotic preparations have been advocated to treat affected horses. Sour milk, a product containing lactose-producing *Streptococcus* species, appears to improve the clinical course greatly in horses suspected of having *Clostridium perfringens* type A infection. Sour milk may benefit the patient by altering the flora and antagonizing enterotoxigenic *C. perfringens* type

A but also is reported to be bactericidal against *C. perfringens* type A.[78] Preparations of *Saccharomyces boulardi* are effective for reducing diarrhea and the frequency of *C. difficile* recurrence in human beings.[83] However, whether relapse is a problem in horses with *C. difficile* colitis is not clear. *Lactobacillus* preparations have a protective effect in human beings and decrease the severity and duration of antibiotic-associated diarrhea.[242,243] However, evidence of their clinical usefulness in horses is lacking.

13.13.5.8 NUTRITION

Good nursing care and adequate nutrition are vital to the treatment of horses with salmonellosis. Salmonellosis is a severely catabolic disease, increasing caloric requirements greatly. Normal intake of roughage to provide energy may be inadequate; however, one should avoid feeding of grains to prevent carbohydrate overload. Dietary management usually consists of restricting or eliminating long-stem roughage (hay) from the diet and feeding exclusively a complete pelleted diet (at least 30% dietary fiber). The rationale behind this recommendation is to reduce the mechanical load on the colon. Frequent meals (4 to 6 times a day) are recommended. One can add corn oil (1 cup every 12 to 24 hours) to the pellets to increase the caloric intake without adding roughage or grain. One should note that if a horse with colitis refuses to eat pelleted feed, then one should feed good-quality grass hay. In anorectic or severely catabolic patients, enteral and parenteral nutrition (total and partial) has been used successfully to provide calories and nutritional support.

13.13.5.9 SPECIFIC THERAPIES

13.13.5.9.1 Strongylosis

Strongylus vulgaris infection requires treatment of the migrating parasite larvae and the lesions produced by the parasite. Fenbendazole (10 mg/kg orally every 24 hours for 3 days or 10 mg/kg orally every 24 hours for 5 days) and ivermectin (200 mg/kg orally) are effective in killing fourth-stage larvae.[121] Other anthelmintics also may be effective when given at higher doses than those required to kill adult worms. The efficacy of these anthelmintics against larvae within thrombi is not known.

Thrombolytic and antithrombotic therapy has been advocated in horses with suspected strongylosis.[121,128] Heparin (20 to 80 IU intravenously or subcutaneously every 6 to 12 hours) is often administered as an anticoagulant. Aspirin (10 to 30 mg/kg orally every 12 to 48 hours) is usually combined with heparin to inhibit platelet adhesion. Aspirin also may inhibit release of platelet products such as thromboxane that affect the motility of the large intestine. Low-molecular-weight dextrans have been advocated as antithrombotics that act by inhibiting platelet function and coagulation.[128,218] The clinical efficacy of dextran administration appears to be good, but no controlled studies have been performed.

13.13.5.9.2 Cyathostomiasis

Anthelmintic administration is usually the only treatment necessary for mild to moderate cases of cyathostomiasis treated early in the course of the disease (within 1 to 3 weeks of onset). Fenbendazole is effective against many larval stages, but resistance is increasing. Although the reported efficacy of ivermectin varies against certain stages,[244] one study reported an overall efficacy of 75%.[245] Currently, fenbendazole (7.5 to 10 mg/kg orally every 24 hours for 5 days) followed on day 6 by ivermectin (200 mg/kg orally) is the most commonly advocated treatment regimen.[133,246] Moxidectin (400 μg/kg orally once

daily) also may be effective against adults and L_3 and L_4 larval stages[247] and may be useful for treating cyathostomiasis. Antiinflammatory therapy also may be beneficial, especially in severe or refractory cases. NSAID administration may have limited value, but dexamethasone appears to be efficacious in refractory cases when used with larvicidal anthelmintics.[133,136] Pretreatment with dexamethasone or prednisolone is indicated before anthelmintic administration if heavy larval loads are suspected to prevent an acute exacerbation of the disease by rapid death of encysted larvae. Bismuth subsalicylate often is administered orally as an antisecretory agent in young animals. Supportive care may be necessary in severe cases, particularly if hypoproteinemia is severe. Horses occasionally require administration of intravenous crystalloid fluids and plasma or other colloids. Proper nutritional support is also important.

13.13.5.9.3 Cantharidin Toxicity

Supportive care is the most important principle of therapy for cantharidin toxicity. Intravenous fluid administration; maintenance of electrolyte balance, especially calcium; and prevention of further renal and urinary tract damage is important.[183,187] Diuresis by intravenous fluid administration is often sufficient to 906
prevent renal failure. Furosemide often is administered after rehydration of the patient to further promote 907
diuresis and to decrease the concentration of the toxin in the urine, which may ameliorate some of the effects on the urinary tract mucosa. Diuresis also has been suggested to increase clearance of the toxin, but no evidence for this has been found. Judicious use of NSAIDs may be necessary to control abdominal pain but should be reserved until the patient is rehydrated and renal failure has been ruled out. Cantharidin is lipid-soluble; therefore oral administration of mineral oil may prevent further absorption of the toxin.[183] Activated charcoal often is administered with the mineral oil.

13.13.5.9.4 Arsenic Toxicity

To reduce arsenic absorption, one should initiate administration of cathartics such as mineral oil and magnesium sulfate slurries and activated charcoal by nasogastric tube immediately. Chelation therapy with sodium thiosulfate 20 to 30 g in 300 ml of water orally and dimercaprol (BAL) 3 mg/kg intramuscularly every 4 hours is indicated.[188] Dimercaprol is a specific antidote for trivalent arsenicals, but its efficacy in horses is questionable. Intravenous fluid administration may help treat shock, replace fluid lost in feces, and promote diuresis but should be monitored carefully because pulmonary edema is a frequent complication. The horse may require more specific treatment of renal, cardiac, pulmonary, or neurologic disease.

13.13.5.9.5 Intestinal Anaphylaxis

Treatment of intestinal anaphylaxis is in principle similar to treatment of other forms of colitis but is often unsuccessful because of the rapidly progressive nature of the syndrome. Inclusion of heparin in intravenous fluids (20 to 80 IU/kg intravenously every 8 to 12 hours) may help prevent vascular thrombosis. Administration of hypertonic saline solutions or colloids may prove to be useful during initial periods of shock. Early treatment with prednisolone succinate (10 to 20 mg/kg intravenously) or dexamethasone (0.1 to 0.2 mg/kg intravenously) may be essential for successful treatment.[192]

13.13.5.9.6 Carbohydrate Overload

Mild cases of carbohydrate overload may not require treatment other than exclusion of grains from the diet for several days to weeks and gradual reintroduction of grain into the diet later if the horse needs the extra energy. Patients showing signs of colic or diarrhea without other systemic signs may benefit from administration of mineral oil, charcoal, and fluids via nasogastric tube. One also may lavage residual carbohydrates from the stomach with the nasogastric tube. NSAIDs such as phenylbutazone (2.2 to 4.4 mg/kg/day intravenously) or flunixin meglumine (1 mg/kg intravenously every 12 hours) often are administered to prevent laminitis. Phenoxybenzamine and heparin given before the onset of laminitis may prevent or decrease the severity of laminitis.[238,248]

More severe cases with dehydrating diarrhea, systemic signs of endotoxemia, or metabolic acidosis require intravenous fluid support to maintain water, electrolyte, and acid-base balance in addition to the previously mentioned treatments. Large amounts of bicarbonate-containing solutions may be required. One should take care when administering hypertonic bicarbonate solutions, because many patients already may be hyperosmotic from lactic acidemia. Isotonic sodium bicarbonate 1.3% may be useful in the hyperosmotic patient. Careful attention to calcium balance is also important, because severe hypocalcemia may occur. One should institute aggressive therapy for systemic inflammation from endotoxemia. One should administer broad-spectrum antibiotics intravenously to combat bacteremia and septicemia, which frequently complicate colitis induced by carbohydrate overload.

In extreme cases, especially if the patient has ingested a large quantity of grain, surgical removal of the grain from the large intestine may be indicated, especially if one can accomplish surgery before the onset of severe clinical signs. However, administration of oral cathartics, such as magnesium sulfate slurries or mineral oil, or a combination of these, is often sufficient to clear the carbohydrates from the large intestine before fermentation, mucosal damage, and absorption of endotoxin and lactic acid occur. Oral administration of activated charcoal may prevent absorption of endotoxin by binding the molecules in the lumen of the bowel. In any case, one should discontinue feeding of the source of the soluble carbohydrates, such as grains. One should feed the horse low-carbohydrate and low-protein roughage such as grass or oat hays until the microbial flora recovers. Oral administration of probiotic preparations containing *Lactobacillus* is contraindicated; however, other sources of normal equine large intestinal microbial flora, such as fecal extracts from normal feces, may be useful to reintroduce appropriate microorganisms. Complications from laminitis and sepsis are common and often cause death.

13.13.5.9.7 Sand Enteropathy

Treatment of sand enteropathy requires removal of the sand from the gastrointestinal tract using psyllium products and magnesium sulfate slurries administered orally. Analgesics may be required initially to relieve pain and stimulate appetite. A diet high in roughage often stimulates further passage of sand. Treatment 907
may require several weeks to remove as much sand as possible. Prevention of the disease is important, and 908
recurrence is not unusual.

13.14

13.14—Ischemic Disorders of the Intestinal Tract

Anthony T. Blikslager

Samuel L. Jones

13.14.1

Strangulating Obstruction

Strangulating obstruction of the intestine is characterized by simultaneous occlusion of the intestinal lumen and its blood supply. Although strangulation of the intestinal lumen results in clinical signs similar to those of simple obstruction, occlusion of the blood supply results in a more rapid deterioration of the intestinal mucosa and subsequent onset of endotoxemic shock. Although a great deal of interest in the relevance and treatment of intestinal reperfusion injury has arisen recently,[1–3] the lesion that develops during strangulation is often severe, leaving little viable bowel for further injury during reperfusion.[2] Although extensive lengths of strangulated small intestine may be resected, strangulation of the large colon presents a much greater treatment dilemma because strangulated intestine usually extends beyond the limits of surgical resection.[4] Therefore horses with large intestinal strangulation often recover with extensive intestinal injury left in place. Thus subtle degrees of reperfusion injury may be important in horses with large colon disease, warranting further work in this area in an attempt to reduce mortality.[3]

913

914

Strangulating obstruction may be divided into hemorrhagic and ischemic forms.[5,6] Hemorrhagic strangulating obstruction, which is most common, involves initial occlusion of veins before occlusion of arteries because of the greater stiffness of arterial walls. This lesion is characterized by a darkened appearance to affected bowel and increased thickness as blood is pumped into the lesion. Ischemic strangulating obstruction occurs if the intestine

is twisted tightly enough to occlude arteries and veins simultaneously. In the case of the colon, such strangulation has been suggested to be determined by how much ingesta is in the colon, because intestinal contents may prevent the intestine from twisting tightly.[7] Tissue involved in ischemic strangulating obstruction appears pale and of normal or reduced thickness because of a complete lack of blood flow (Figure 13.14-1). Bowel peripheral to strangulating lesions also may become injured because of distention, which reduces mural blood flow once it reaches critical levels. Furthermore, as this intestine is decompressed, it also may undergo reperfusion injury.[8–10]

Figure 13.14-1 Ischemic strangulating obstruction of the small colon by a mesenteric lipoma. **A,** The lipoma *(arrow)* has encircled a segment of small colon tightly. **B,** Following resection of the lipoma, a pale area of strangulated small colon clearly is demarcated *(arrows),* the appearance of which is consistent with ischemic strangulating obstruction.

13.14.2 Small Intestinal Strangulation

13.14.2.1 CLINICAL SIGNS

Horses with small intestinal strangulating obstruction typically have moderate to severe signs of abdominal pain that are only intermittently responsive to analgesic medications. During the latter stages of the disease process, horses may become profoundly depressed rather than painful as affected intestine necroses. Horses have progressive signs of endotoxemia, including congested mucous membranes, delayed capillary refill time, and an elevated heart rate (>60 beats/min in most cases). In addition, one typically obtains reflux following passage of a stomach tube, and one usually can detect loops of distended small intestine on rectal palpation of the abdomen.[11] However, these latter findings vary depending on the duration and location of the obstruction. For example, horses with ileal obstructions tend to reflux later in the course of the disease process than horses with a jejunal obstruction. Furthermore, a horse that has an entrapment of small intestine in the epiploic foramen may not have palpable loops of small intestine because of the cranial location of these structures.[12] Abdominocentesis can provide critical information on the integrity of the intestine and is indicated in horses in which one suspects strangulation of the small intestine.[13] A horse that has signs compatible with a small intestinal obstruction and additionally has serosanguinous abdominal fluid with an elevated protein level (>2.5 914

mg/dl) is likely to require surgery, although one must differentiate these cases from proximal enteritis. In general, horses with small intestinal strangulation show continued signs of abdominal pain, whereas horses with proximal enteritis tend to be depressed after initial episodes of mild abdominal pain. In addition, horses with small intestinal strangulation continue to deteriorate clinically despite appropriate medical therapy and will likely begin to show an increased white blood cell count (>10,000 cells/μl) in the abdominal fluid as the duration of strangulation increases. However, cases occur in which the differentiation between small intestinal strangulation and proximal enteritis is not clear, at which point one may elect surgery rather than risking delay of abdominal exploration of a horse with a potential strangulating lesion.[14]

13.14.2.2 PROGNOSIS

The prognosis for survival in horses with small intestinal strangulating lesions is generally lower than for most forms of colic.[15] However, recent studies indicate that in excess of 80% of horses with small intestinal strangulating lesions are discharged from the hospital.[16] Nonetheless, veterinarians should warn owners that the long-term survival rates are reduced substantially to below 70%,[17] in part because of long-term complications such as adhesions.[18,19] In addition, the prognosis is particularly low for some forms of strangulation, including entrapment of small intestine within a mesenteric rent.[20]

13.14.2.3 EPIPLOIC FORAMEN ENTRAPMENT

The epiploic foramen is a potential opening (because the walls of the foramen are usually in contact) to the omental bursa located within the right cranial quadrant of the abdomen. The foramen thus is bounded dorsally by the caudate process of the liver and caudal vena cava and ventrally by the pancreas, hepatoduodenal ligament, and portal vein. Intestine may enter the foramen from the visceral surface of the liver toward the right body wall or the opposite direction. Studies differ as to which is the most common form.[12,21] In the case of entrapments that enter the foramen in a left-to-right direction, the omental bursa ruptures as the intestine migrates through the epiploic foramen, which may contribute to intraabdominal hemorrhage often seen with this condition. Clinical signs include acute onset of severe colic with examination findings compatible with small intestinal obstruction. The condition tends to be more prevalent in older horses,[12] possibly because of enlargement of the epiploic foramen as the right lobe of the liver undergoes age-associated atrophy.[22] However, the disease also has been recognized in foals as young as 4 months of age.[23] One makes a definitive diagnosis at surgery, although ultrasonographic findings of distended loops of edematous small intestine adjacent to the right middle body wall suggest epiploic foramen entrapment.[12] In general, thickened, amotile intestine on ultrasonographic examination is highly predictive for small intestinal strangulating obstruction.[24] Small intestine entrapped in the epiploic foramen may be limited to a portion of the intestinal wall (parietal hernia),[25] and the large colon may become entrapped within the epiploic foramen.[26] In treating epiploic foramen entrapment, one must not enlarge the epiploic foramen by blunt force or with a sharp instrument, because rupture of the vena cava or portal vein and fatal hemorrhage may occur. Prognosis has improved substantially over the last decade, with current short-term survival rates (discharge from the hospital) ranging from 74%[27] to 79%.[12] Preoperative abdominocentesis has been found consistently to be the most predictive test of postoperative survival.[12,27]

13.14.2.4 STRANGULATION BY PEDUNCULATED MESENTERIC LIPOMA

Lipomata form between the leaves of the mesentery as horses age and develop mesenteric stalks as the weight of the lipoma tugs on the mesentery. The stalk of the lipoma subsequently may wrap around a loop of small intestine or small colon causing strangulation. One should suspect strangulating lipomata in aged (>15 years old) geldings with acute colic referable to the small intestinal tract.[28,29] Ponies also appear to be at risk of developing disease,[29] suggesting alterations in fat metabolism may predispose certain horses to development of mesenteric lipomata. One usually makes the diagnosis at surgery, although on rare occasions one can palpate a lipoma per rectum.[30] Treatment involves surgical resection of the lipoma and strangulated bowel, although strangulated intestine is not always nonviable.[28] Studies indicate that approximately 50%[29] to 80%[28] of horses are discharged from the hospital following surgical treatment.

13.14.2.5 SMALL INTESTINAL VOLVULUS

A volvulus is a twist along the axis of the mesentery, whereas torsion is a twist along the longitudinal axis of the intestine. Small intestinal volvulus theoretically is initiated by a change in local peristalsis or the occurrence of a lesion around which the intestine and its mesentery may twist (such as an ascarid impaction).[11] Volvulus is reportedly one of the most commonly diagnosed causes of small intestinal obstruction in foals.[31,32] The theory is that young foals may be at risk of small intestinal volvulus because of changing feed habits and adaptation to a bulkier adult diet. Onset of acute, severe colic, a distended abdomen, and radiographic evidence of multiple loops of distended small intestine in a young foal suggest small intestinal volvulus. However, one cannot differentiate volvulus from other causes of small intestinal obstruction preoperatively. In 915
adult horses, volvulus frequently occurs in association with another disease process, during which small 916
intestinal obstruction results in distention and subsequent rotation of the small intestine around the root of the mesentery. Although any segment of the small intestine may be involved, the distal jejunum and ileum are affected most frequently because of their longer mesenteries.[11] One makes the diagnosis at surgery by palpating a twist at the origin of the cranial mesenteric artery. Treatment includes resection of devitalized bowel, which may not be an option because of the extent of small intestinal involvement (similar to large colon volvulus). Prognosis is based on the extent of small intestine involved and its appearance following surgical correction of the lesion. In general, horses with greater than 50% of the small intestine devitalized are considered to have a grave prognosis.[33]

13.14.2.6 STRANGULATION VIA MESENTERIC OR LIGAMENTOUS RENTS

A number of structures, when torn, may incarcerate a segment of intestine (typically the small intestine), including intestinal mesentery,[20] the gastrosplenic ligament,[34] the broad ligament,[35] and the cecocolic ligament.[36] Horses with such incarcerations have signs typical of a horse with strangulating small intestine, including moderate to severe signs of abdominal pain, endotoxemia, absent gastrointestinal sounds, distended small intestine on per rectal palpation, nasogastric reflux, and serosanguinous abdominal fluid. However, the prognosis for many of these horses appears to be lower than for horses with other types of small intestinal strangulations. For example, in horses with small intestine entrapped in a mesenteric rent, only 7 of 15 horses were discharged from the hospital, and only 2 of 5 horses for which follow-up information was available survived long term (>5 months).[20] Poor outcome may result from the difficulty in unentrapping incarcerated intestine, the degree of hemorrhage, and the length of intestine affected.

13.14.2.7

INGUINAL HERNIA

Inguinal herniae are more common in Standardbred and Tennessee Walking horses that tend to have congenitally large inguinal canals.[11] Inguinal herniae also may occur in neonatal foals but differ from herniae in mature horses in that they are typically nonstrangulating. The nature of the hernia (direct versus indirect) is based on the integrity of the parietal vaginal tunic. In horses in which the bowel remains within the parietal vaginal tunic, the hernia is referred to as indirect, because strictly speaking the bowel remains within the peritoneal cavity. Direct herniae are those in which strangulated bowel ruptures through the parietal vaginal tunic and occupies a subcutaneous location. These direct herniae most commonly occur in foals and should be suspected when a congenital inguinal hernia is associated with colic, swelling that extends from the inguinal region or the prepuce, and intestine that may be palpated subcutaneously.[37,38] Although most congenital indirect inguinal herniae resolve with repeated manual reduction or application of a diaper, surgical intervention is recommended for congenial direct herniae.[37]

Figure 13.14-2 Inguinal hernia in a horse with colic. The enlarged testicle has compromised venous drainage because of herniated small intestine within the inguinal canal.

Historical findings in horses with strangulating inguinal herniae include acute onset of colic in a stallion that recently had been used for breeding. A cardinal sign of inguinal herniation is a cool, enlarged testicle on one side of the scrotum (Figure 13.14-2).[39,40] However, inguinal herniae also have been reported in geldings.[41] One also can detect inguinal herniae on rectal palpation, and one can use manipulation of herniated bowel per rectum to reduce a hernia, but this is generally not recommended because of the risk of rectal tears. In many cases, the short segment of herniated intestine greatly improves in appearance after reduction and in some

cases can be left unresected. The affected testicle will be congested because of vascular compromise within the spermatic cord, and although the testicle may remain viable, resection generally is recommended.[42] The prognosis in adult horses is good, with up to 75% of horses surviving to 6 months.[40] Horses that have been treated for inguinal herniae may be used for breeding. In these horses, the remaining testicle will have increased sperm production, although an increased number of sperm abnormalities will be noticeable following surgery because of edema and increased temperature of the scrotum.

13.14.2.8 STRANGULATING UMBILICAL HERNIAE

Although umbilical herniae are common in foals, strangulation of herniated bowel is rare. In one study, 6 of 916 147 (4%) horses with umbilical herniae had incarcerated intestine.[43] Clinical signs include a warm, swollen, 917 firm, and painful hernia sac associated with signs of colic. The affected segment of bowel is usually small intestine, but herniation of cecum or large colon also has been reported. In rare cases, one may find a hernia that involves only part of the intestinal wall, called a Richter's hernia. In foals that have a Richter's hernia, an enterocutaneous fistula may develop. In one study, 13 of 13 foals with strangulating umbilical herniae survived to discharge, although at least 3 died of long-term complications.[44]

13.14.2.9 INTUSSUSCEPTIONS

An intussusception involves a segment of bowel (intussusceptum) that invaginates into an adjacent aboral segment of bowel (intussuscipiens). The reason for such invagination is not always clear but may involve a lesion at the leading edge of the intussusception, including small masses, foreign bodies, or parasites. In particular, tapeworms *(Anoplocephala perfoliata)* have been implicated.[45] Ileocecal intussusceptions are the most common intestinal intussusceptions in the horse and typically affect young animals. In one study evaluating 26 cases of ileocecal intussusception, the median age of the horses was 1 year old. Acute ileocecal intussusceptions are those in which the horses has a duration of colic of less than 24 hours and involve variable lengths of intestine that ranged in one study from 6 to 457 cm long. In acute cases the involved segment of ileum typically has a compromised blood supply. Chronic ileocecal intussusceptions typically involve short segments of ileum (up to 10 cm long), and the ileal blood supply is frequently intact.[46] Abdominocentesis results vary because strangulated bowel is contained within the adjacent bowel. Obstruction of the small intestine often is evident, including nasogastric reflux and multiple distended loops of small intestine on rectal palpation. Horses with chronic ileocecal intussusceptions have mild, intermittent colic, often without evidence of small intestinal obstruction. In one study, a mass was palpated in the region of the cecal base in approximately 50% of cases.[45] Transabdominal ultrasound may be helpful in discerning the nature of the mass. The intussusception has a characteristic target appearance on cross section.[47] Other segments of the small intestine also may be intussuscepted, including the jejunum (Figure 13.14-3). In one study of 11 jejunojejunal intussusceptions, the length of bowel involved ranged from 0.4 to 9.1 m.[48] Attempts to reduce intussusceptions at surgery are usually futile because of intramural swelling of affected bowel. One should resect jejunojejunal intussusceptions.

For acute ileocecal intussusceptions, one should transect the small intestine as far distally as possible and perform a jejunocecal anastomosis. In horses with particularly long intussusceptions (up to 10 m has been reported), one may attempt an intracecal resection.[49] For horses with chronic ileocecal intussusceptions, one should perform a jejunocecal bypass without small intestinal transection. The prognosis is good for horses

with chronic ileocecal intussusceptions and guarded to poor for horses with acute ileocecal intussusceptions, depending on the length of bowel involved.[46]

Figure 13.14-3 Jejunojejunal intussusception in a horse presented for colic. The intussusceptum has become ischemic because of invagination of intestine and its mesenteric blood supply into the intussuscipiens.

13.14.2.10 DIAPHRAGMATIC HERNIAE

Herniation of intestine through a rent in the diaphragm is rare in the horse and may involve any segment of bowel, although small intestine is herniated most frequently. Diaphragmatic rents may be congenital or acquired, but acquired herniae are more common. Congenital rents may result from incomplete fusion of any of the four embryonic components of the diaphragm: pleuroperitoneal membranes, transverse septum, and esophageal mesentery. In addition, abdominal compression of the foal at parturition may result in a congenital hernia.[50] Acquired herniae are presumed to result from trauma to the chest or a sudden increase in intraabdominal pressure, such as might occur during parturition, distention of the abdomen, a sudden fall, or strenuous exercise.[51] Herniae have been found in a number of different locations, although large congenital herniae are typically present at the ventral most aspect of the diaphragm, and most acquired herniae are located at the junction of the muscular and tendinous portions of the diaphragm.[50] A peritoneopericardial hernia has been documented in at least one horse.[52]

917

Clinical signs usually are associated with intestinal obstruction rather than respiratory embarrassment.[51] However, careful auscultation may reveal an area of decreased lung sounds associated with obstructed intestine and increased fluid within the chest cavity.[53] Such signs may prompt thoracic radiography or ultrasound, both of which one can use to make a diagnosis. Auscultation also may reveal thoracic intestinal sounds, but differentiating these from sounds referred from the abdomen typically is not possible. In one report, two of three horses diagnosed with small intestinal strangulation by diaphragmatic hernia had respiratory acidemia attributable to decreased ventilation.[54] Treatment of horses with diaphragmatic hernia is fraught with compli cations because of the need to reduce and resect strangulated bowel and the need to repair the defect in the diaphragm.[55,56] Because dorsal defects in the diaphragm are among the common forms of diaphragmatic defect, closing the diaphragmatic hernia via the approach used for abdominal exploration may not be possible. However, because herniation is likely to recur,[55] scheduling a second surgery using an appropriate approach to resolve the diaphragmatic defect is appropriate.

13.14.3 Large Colon Volvulus

13.14.3.1 CLINICAL SIGNS

Horses with large colon volvulus have rapid onset of severe, unrelenting abdominal pain, most often in postpartum broodmares.[4] Once the large colon strangulates (≥270-degree volvulus), gas distention is significant, leading to gross distention of the abdomen, compromised respiration as the distended bowel presses up against the diaphragm, and visceral pooling of blood as the caudal vena cava is compressed. Horses with this condition are frequently refractory even to the most potent of analgesics. These horses may prefer to lie in dorsal recumbency, presumably to take weight off the strangulated colon. An abbreviated physical examination is warranted in these cases, because the time elapsed from the onset of strangulation to surgical correction is critical. Under experimental conditions, the colon is irreversibly damaged within 3 to 4 hours of a 360-degree volvulus of the entire colon.[57] Despite severe pain and hypovolemia, horses may have a paradoxically low heart rate, possibly related to increased vagal tone. In addition, results of abdominocentesis often do not indicate the degree of colonic compromise[4,58] and in many cases are not worth attempting because of extreme colonic distention.[59] Palpation per rectum reveals severe gas distention of the large colon, often restricting access to the abdomen beyond the pelvic brim. One may make the diagnosis tentatively based on signalment, severity of pain, and degree of distention.

13.14.3.2 SURGICAL FINDINGS

At surgery, the volvulus typically is located at the mesenteric attachment of the colon to the dorsal body wall and the most common direction of the twist is dorsomedial using the right ventral colon as a reference point. However, the colon may twist in the opposite direction, twist greater than 360 degrees (up to 720 degrees has been reported) or twist at the level of the diaphragmatic and sternal flexures.[4] In all cases, one should decompress the colon as much as possible, and in many cases a colonic evacuation via a pelvic flexure enterotomy greatly aids correction of the volvulus. One must determine after correction of the volvulus whether the colon has been injured irreversibly and should base the determination on mucosal color and bleeding (if an enterotomy has been performed), palpation of a pulse in the colonic arteries, serosal color, and appearance of muscular motility. If one judges the colon to be damaged irreversibly, one can consider the feasibility of a large colon resection. Although 95% of the colon can be resected (that part of the colon distal

to the level of the cecocolic fold), damage from the volvulus usually exceeds that which can be resected. In these cases, surgeons may elect to resect as much damaged bowel as possible or may advise euthanasia.[7]

13.14.3.3 PROGNOSIS

The prognosis is guarded to poor because of the rapid onset of this disease. In one study the survival rate was 35%.[58] In a more recent report the survival rate was 36% for horses with 360-degree volvulus of the large colon compared with 71% for horses with 270-degree volvulus.[4] However, one study in central Kentucky documented a high success rate, possibly because of early recognition of the disease and the proximity of the hospital to the surgical caseload.[60] Postoperative complications include hypovolemic and endotoxic shock, extensive loss of circulating protein, disseminated intravascular coagulation, and laminitis. In addition, large colon volvulus has a propensity to recur. Although one study documented a recurrence rate of less than 5%,[58] some authors believe recurrence may be as high as 50%.[7] Therefore one should consider methods to prevent recurrence in patients at risk of recurrence, particularly broodmares that tend to suffer from the disease recurrently during the foaling season.[61,62]

13.14.4 Other Causes of Large Intestinal Ischemia

The most common intussusceptions of the large intestine are cecocecal and cecocolic intussusceptions.[63,64] Both are likely attributable to the same disease process, with variable inversion of the cecum. These conditions tend to occur in young horses (63% were less than 3 years old in one study) and may be associated with intestinal tapeworms. Horses show highly variable clinical signs, including acute severe colic, intermittent pain over a number of days, or chronic weight loss.[64] These variable presentations likely relate to the degree to which the cecum has intussuscepted. Initially, the cecal tip inverts, creating a cecocecal intussusception, which does not obstruct flow of ingesta. As the intussusception progresses, the cecum inverts into the right ventral colon (cecocolic intussusception), obstructs flow of ingesta, and often causes severe colic. The cause of abdominal pain is often difficult to differentiate in these cases, although detecting a mass on the right side of the abdomen by per rectal palpation or ultrasound examination sometimes is possible.[63,64] Treatment involves manual surgical reduction by retracting the intussusceptum directly[63] or via an enterotomy in the right ventral colon.[65] However, a number of cases occur in which one cannot reduce the cecum readily because of severe thickening or in which surgical procedures result in fatal contamination. For example, one report stated that 8 of 11 horses were euthanized in the perioperative period because of complications,[63] and another report stated that 12 of 30 horses were euthanized before or during surgery. The latter included all of the horses with chronic disease because of irreversible changes to the cecum.[64] However, one recent report on cecocolic intussusceptions indicated that seven of eight horses that underwent right ventral colon enterotomy and cecal resection survived long-term,[65] suggesting that continued improvements in surgical techniques may improve the prognosis.

Colocolic intussusceptions are rare but have been reported to affect the pelvic flexure and the left colons.[66–69] Although the condition is reported to be more common in young horses,[67–69] the condition may affect older horses.[66] Clinical findings may include a palpable mass on the left side of the abdomen.[67] Ultrasonography also may be useful. Treatment requires manual reduction of the intussusception at surgery,[67,69] or resection of affected bowel.[66] Because the left colons may be exteriorized extensively and manipulated at surgery,[66–69] the prognosis is fair.

13.14.5 Rectal Prolapse

Rectal prolapse may occur following any disease that causes tenesmus, including diarrhea, rectal neoplasia, and parasitism,[70] or prolapse can occur following elevations in intraabdominal pressure during parturition or episodes of coughing.[71,72] Rectal prolapses are classified into four categories (Table 13.14-1) based on the extent of tissue prolapsed and the severity. Type I rectal prolapse is most common and is characterized by a doughnut-shaped prolapse of rectal mucosa and submucosa. Type II prolapses involve full-thickness rectal tissue, whereas type III prolapses additionally have invagination of small colon into the rectum. Type IV prolapses involve intussusception of proximal rectum or small colon through the anus in the absence of prolapse of tissue at the mucocutaneous junction at the anus.[73] One can differentiate type IV from other forms of prolapse by their appearance and a palpable trench between prolapsed tissue and the anus.

TABLE 13.14-1 Classification of Rectal Prolapse

GRADE	DESCRIPTION	PROGNOSIS
I	Prolapse of rectal mucosa	Good
II	Prolapse of full-thickness rectum	Fair
III	Grade II prolapse with additional protrusion of small colon	Guarded
IV	Intussusception of rectum and small colon through the anus	Poor

Type I prolapses occur most frequently in horses with diarrhea, in which the rectal mucosa becomes irritated and protrudes intermittently during episodes of tenesmus. If tenesmus persists, rectal mucosa can remain prolapsed. Rectal mucosa rapidly becomes congested and edematous under these conditions, which one should treat with osmotic agents such as glycerin or magnesium sulfate and by massaging and reducing the prolapse.[74] A purse-string suture may be required to keep the mucosa inside the rectum. Topical application of lidocaine solution or jelly, epidural anesthesia, and sedation may help reduce tenesmus that incites and exacerbates rectal prolapse. One can apply similar treatments to type II rectal prolapses. However, these more severe prolapses may not be reducible without surgical resection of mucosa and submucosa from the prolapsed bowel.[70,74]

Type III and IV rectal prolapses are more serious injuries because of involvement of small colon.[75] In horses with type III prolapses, one should perform an abdominocentesis to determine if injured small colon has resulted in peritonitis. One should reduce the small colon component manually if possible, although prolapsed rectal tissue typically requires mucosal/submucosal resection. One should perform surgical exploration of the abdomen to determine the status of the small colon, although one can use serial abdominocenteses in lieu of surgery to detect progressive necrosis of bowel. Type IV prolapses occur most commonly in horses with dystocia.[73] These prolapses are almost always fatal because of stretching and tearing of mesenteric vasculature, with subsequent 919
infarction of affected bowel. Therefore euthanasia usually is warranted based on physical examination findings. 920
However, confirmation of severe small colonic injury requires abdominal exploration via a midline approach or laparoscopy.[76] A horse with compromised small colon conceivably could undergo a colostomy of the proximal small colon, but the compromised small colon typically necroses beyond that which can be resected via a midline abdominal approach.[74]

13.14.6 Nonstrangulating Infarction

Nonstrangulating infarction occurs following cranial mesenteric arteritis caused by migration of *Strongylus vulgaris* and has become a rare disorder since the advent of broad-spectrum anthelmintics. Although thromboemboli have been implicated in the pathogenesis of this disease, careful dissection of naturally occurring lesions has not revealed the presence of thrombi at the site of intestinal infarctions in most cases.[77] These findings suggest that vasospasm plays an important role in this disease.[78] Clinical signs vary greatly depending on the extent to which arterial flow is reduced and the segment of intestine affected. Any segment of intestine supplied by the cranial mesenteric artery or one of its major branches may be affected, but the distal small intestine and large colon are more commonly involved. No clinical variables exist that one can use to differentiate this disease from strangulating obstruction reliably. In some cases, massive infarction results in acute, severe colic.[77] Occasionally, one may detect an abnormal mass and fremitus on palpation of the root of the cranial mesenteric artery per rectum. One should consider this disease a differential diagnosis in horses with a history of inadequate anthelmintic treatment and the presence of intermittent colic that is difficult to localize. Although one should perform fecal parasite egg counts, they are not indicative of the degree of parasitic infestation.

In addition to routine treatment of colic, dehydration, and endotoxemia, medical treatment may include aspirin (20 mg/kg every 24 hours) to decrease thrombosis.[78] Definitive diagnosis requires surgical exploration. However, these cases are difficult to treat because of the patchy distribution of the lesions and the possibility of lesions extending beyond the limits of surgical resection. In addition, further infarction may occur following surgery. The prognosis is fair for horses with intermittent mild episodes of colic that may be amenable to medical therapy but is poor in horses that require surgical intervention.[77,78]

13.15

13.15—Obstructive Disorders of the Gastrointestinal Tract

Anthony T. Blikslager

Samuel L. Jones

13.15.1

Approach to the Horse With Colic

Clinical management of colic is distinctly different from management of many other clinical syndromes because the initial focus is often not on defining the definitive diagnosis but rather on deciding whether a horse requires surgical exploration. Therefore the clinician must collect historical, physical examination, and clinicopathologic information and make a decision whether these findings warrant medical management or whether to perform surgical exploration of the abdomen because of a suspected obstructive or ischemic lesion. For example, one may examine a horse with signs of severe abdominal pain, poor cardiovascular status, and abdominal distention that may be compatible with an extensive list of differential diagnoses but that more importantly indicate the need for abdominal exploration to minimize the extent of intestinal injury. The speed with which one can make this clinical decision has a tremendous effect on the well-being of the patient,[1,2] because delaying surgical exploration of a horse with on-going intestinal injury exacerbates shock induced largely by endotoxin traversing damaged mucosa, and this in turn correlates with mortality.[3]

13.15.1.1

HISTORY

The initial clinical step in the workup of horses with colic is taking a thorough history. However, one may have to delay taking a complete history until after the physical examination and initial treatment, because management of abdominal pain may take precedence. If possible, one should obtain the vital components of the history before examination and treatment: the duration and severity of colic symptoms, analgesics already administered, and a history of any adverse drug reactions. The two most critical factors from a history that would support a decision to explore a horse with colic surgically are the duration of signs and the extent of pain. One deduces the latter from asking the owner about the presence and frequency of pawing, looking at the flanks, rolling, repeatedly going down and getting back up, posturing as if to lie down or urinate, among other clinical evidence of pain.[4] Table 13.15-1 lists other important components of the history one should obtain to try to ascertain why colic has occurred.

13.15.1.2

PHYSICAL EXAMINATION FINDINGS

Just as the history necessarily may need to be brief to allow rapid treatment of colic, so the clinician must be able to alter the extent of the physical examination to treat the horse in a timely fashion. The most critical

examination finding is the heart rate of the horse, because it provides an excellent assessment of the cardiovascular status of the horse.[4] The heart rate is likely the single most reliable predictor of the need for surgery and survival.[4,5] Because analgesics can alter the heart rate dramatically, if possible, one should obtain the heart rate before administering analgesics. Other components of the examination are designed specifically to gather information about the cardiopulmonary status of the horse (quality of the pulse, mucous membrane color, capillary refill time, respiratory rate, and full auscultation of the chest), and the nature of the intestinal obstruction (auscultation of gastrointestinal sounds, per rectal palpation of the abdomen, and presence of nasogastric reflux). Although classic presentations exist for horses with obstructions of the small or large intestine (Table 13.15-2), clinical presentations of the various types of intestinal obstructions can vary. For example, a horse that has a small intestinal obstruction may have several loops of distended small intestine without any evidence of gasric fluid accumulation (assessed as nasogastric reflux), depending on the site (distal versus proximal), extent, and duration of the obstruction. Other examples include horses with large 922
colon obstruction that may have gastric fluid accumulation because of direct compression of the small 923
intestine by distended colon or via tension on the duodenocolic ligament. The most useful diagnostic test for determining the type of intestinal obstruction is rectal palpation of the abdomen.[4] However, one can reach only approximately one third of the abdomen via the rectum, and this percentage may be substantially less in large horses or heavily pregnant horses. Nonetheless, attempting to determine the type of obstruction present (small intestine versus large intestine, and simple obstruction versus strangulating obstruction) is worthwhile; this information directly affects prognosis. In one study, interns and residents at a veterinary teaching hospital were able to predict the type of lesion with a specificity exceeding 90%.[6] Findings from palpation are helpful in educating the client about the potential findings in surgery and the likelihood of survival for the horse.

TABLE 13.15-1 History Findings and Their Relevance to Colic and Its Prevention

COMPONENT OF HISTORY	RISK FOR COLIC	POTENTIAL MECHANISMS
Feeding	Recent change in feed	Alteration in fluid flux or fermentation in the large colon
	Coastal Bermuda hay with a high fiber content	Obstruction of ileum by fine, fibrous hay
	Feeding round bales	Poor-quality hay
	Feeding off the ground	Horses may ingest sand in some regions of the country
	Excessive concentrate	Alteration in fluid flux or fermentation in the large colon
	Large, infrequent meals	Alteration in fluid flux or fermentation in the large colon
	Bolting feed	Large boluses of feed entering the esophagus and stomach
Environment	Excessive time in stall	Insufficient intake of roughage
		Insufficient exercise
	Insufficient access to water	Dehydration
Exercise	Exercise-induced exhaustion	Dehydration
		Reduced gastrointestinal motility
Preventive care	Insufficient dental care	Poor mastication of feed
	Insufficient anthelmintic treatment	Large parasite burden
Medication	Excessive administration of nonsteroidal antiinflammatory drugs	Mucosal damage, particularly in the stomach and colon
Previous medical history	Colic surgery	Adhesions
		Anastomotic obstruction

TABLE 13.15-2 Indications for Surgery in Patients With Colic According to Their Clinical Signs

INDICATION	CLINICAL SIGNS
Refractory pain	Repeated episodes of pain despite treatment with analgesics
	Violent episodes of pain
	Persistently elevated heart rate (>48 beats/min)
Endotoxemia in the face of colic	Persistently elevated heart rate
	Weak peripheral pulse
	Abnormal mucous membrane color (pale, hyperemic, purple)
	Delayed capillary refill time (>2 seconds)
Evidence of a refractory small intestinal obstruction	Refractory pain
	Nasogastric reflux
	Distended loops of small intestine on per rectum palpation
Evidence of a refractory large intestinal obstruction	Refractory pain
	Abdominal distention
	Distended large colon on per rectum palpation
	Tight band(s) on per rectum palpation
Evidence of devitalized bowel	Endotoxemia
	Abnormal abdominocentesis (total protein >2.5 g/dl, total nucleated cell count >10,000/l)

13.15.1.3 MANAGEMENT OF ABDOMINAL PAIN

Before considering how to manage signs of colic, one should remember that such signs are poorly localized. Therefore although colic is most frequently associated with intestinal disease, one should consider dysfunction of other organ systems, including urinary obstruction,[7,8] biliary obstruction,[9] uterine torsion or tears,[10,11] ovarian artery hemorrhage,[10] and neurologic disease as differential diagnoses.[12] However, the duration and 923
severity of colic signs are excellent predictors of whether a horse requires surgical exploration of the 924
abdomen. In fact, refractory pain supersedes all other predictors of the need for surgery in the colic patient. Once signs of colic have been recognized and categorized as to their severity, rapidly and effectively relieving the pain is critical for the well-being of the horse and to reduce the owner's anxiety. In addition, pain is best managed before it becomes severe.[13] Several classes of analgesics are readily available to treat horses with colic (Table 13.15-3), including α_2-agonists (xylazine, detomidine), opiates (butorphanol), and nonsteroidal antiinflammatory drugs (NSAIDs, such as flunixin meglumine). Although much of this information is familiar to most practitioners, several principles deserve emphasis. The short-duration drugs xylazine and butorphanol,

which provide analgesia for 30 to 45 minutes, allow the veterinarian to determine if pain is recurrent within the time period of the typical examination. In contrast, flunixin meglumine is not as potent as an analgesic but has a much longer duration of action. To avoid deleterious effects on gastrointestinal mucosa and the kidneys, one should not administer flunixin meglumine more frequently than recommended.[14,15] The recent discovery of two isoforms of cyclooxygenase (COX), the enzyme inhibited by NSAIDs, has resulted in discovery of drugs that can more selectively inhibit proinflammatory COX-2 while permitting continued constitutive production of prostanoids. Such specificity may be advantageous in horses with colic, particularly when one considers recent evidence of reduced intestinal recovery from an ischemic event with flunixin compared with a drug that is more selective for COX-2.[16] One should reserve the α_2-agonist detomidine for horses with severe, unrelenting pain because of its tremendous potency.[17] In addition, one should remember that α_2-agonists reduce the heart rate associated with a transient increase in blood pressure,[18,19] thereby reducing the predictive value of the heart rate and pulse pressure.

TABLE 13.15-3 Analgesics Commonly Used to Treat Colic in Horses

DRUG	DOSAGE	AMOUNT FOR AN ADULT HORSE
Butorphanol	0.025–0.05 mg/kg as needed	5–10 mg
Detomidine	10–20 μg/kg as needed	5–10 mg
Flunixin	0.25–1.1 mg/kg every 8 to 12 hours[*]	125–500 mg
Xylazine	0.3–0.5 mg/kg as needed	150–250 mg

* The longer treatment interval corresponds to the higher dose, whereas lower doses may be given more frequently.

13.15.1.4 CLINICAL PATHOLOGY

The most immediately useful clinicopathologic information in horses with colic are the packed cell volume and total protein, because one can use them to substantiate clinical estimates of dehydration and they correlate strongly with prognosis.[20,21] A serum biochemical profile is useful for assessing electrolyte imbalances, tissue perfusion (anion gap or lactate), and kidney and liver function. One can use serum biochemical or blood gas analysis to assess acid-base status. Horses with colic most frequently show evidence of metabolic acidosis associated with poor tissue perfusion caused by hypovolemia or endotoxemia, but one may note other abnormalities such as metabolic alkalosis in association with extensive loss or sequestration of stomach chloride. Metabolic acidosis has been investigated further in horses with colic by measuring blood lactate, although this test is not offered routinely in many laboratories. Lactate levels also have been inferred from measurement of the anion gap, although one study noted that lactate in horses with colic did not account for the entire anion gap.[22] Lactate levels and anion gap closely correlate with prognosis for survival.[20,23,24]

Other key components of assessment of the horse with colic are abdominocentesis and complete blood count. The total white blood cell count and differential can provide crucial evidence of systemic inflammation associated with endotoxemia stemming from colic attributable to colitis (leukopenia, neutropenia, and a left shift) rather than an obstruction (highly variable complete blood count findings). Peritoneal fluid may be helpful in determining the integrity of the intestine. Specifically, as the intestine becomes progressively

devitalized, the peritoneal fluid becomes serosanguinous as red blood cells leak into the abdomen, followed by an elevation in the total protein (>2.5 g/dl) and progressive increases in total nucleated cell count (>10,000 cells/μl). However, these findings do not always correlate well with the condition of the intestine, particularly in horses with large colon volvulus. For example, in a study of 57 horses with large colon volvulus, the average total protein (2.5 g/dl) and total nucleated cell count (1000 cells/μl) were normal despite the fact that only 36% with a 360-degree volvulus survived.[4,25] These measures may appear normal because the development of severe mucosal injury following large colon volvulus is rapid and may not allow enough time for protein and leukocytes to equilibrate with the abdominal fluid.[26]

Investigators have taken all the variables routinely assessed during evaluation of horses for colic and have attempted to develop models to predict accurately the need for surgery and the prognosis for life.[27–30] None of these predictor models has taken the place of clinical decision making, although these studies have added 924
tremendously to understanding of the importance of some prognostic factors, particularly those reflecting 925
cardiovascular function.

13.15.2 Small Intestinal Simple Obstruction

Simple obstruction involves intestinal obstruction of the lumen without obstruction of vascular flow. However, because a tremendous volume of fluid enters the small intestinal lumen daily,[31,32] the obstructed intestine tends to become distended, which in turn may reduce mural blood flow.[33] Ultimately, such distention may result in necrosis of tissues, particularly in the immediate vicinity of the obstruction.[34] Few are the causes of simple obstruction in the small intestine, and the incidence of these obstructions is low (approximately 3% of all referred horses in one large hospital-based study).[5] However, in some geographic regions, this type of obstruction is prevalent. For example, in the southeastern United States, ileal impactions are common.[35,36]

13.15.2.1 ASCARID IMPACTIONS

Impactions caused by *Parascaris equorum* typically occur in foals under 6 months of age that have been on a poor deworming program and have a heavy parasite burden. Products that cause sudden ascarid death, including piperazine, organophosphates, and pyrantel pamoate, have been incriminated in triggering acute intestinal obstruction by dead parasites. Ascarids are particularly problematic because of the large size of the adult parasite (Figure 13.15-1). Clinical signs include acute onset of colic following administration of an anthelmintic and signs compatible with small intestinal obstruction, including nasogastric reflux. Occasionally, dead parasites are present in the reflux. The onset of the disease varies according to the degree of obstruction. One tentatively may base diagnosis on the history and signs referable to small intestinal obstruction. Abdominal radiographs may indicate the presence of multiple loops of distended small intestine but are not required if clinical signs indicate the immediate need for surgery. Initial medical treatment should include treatment of hypovolemic shock resulting from sequestration of fluid in the small intestine and systemic inflammation from absorption of endotoxin. Surgical treatment typically involves an enterotomy made over the intraluminal impaction and removal of ascarids. The prognosis is fair in horses that are rapidly and appropriately treated but poor in foals with evidence of hypovolemic and endotoxic shock.[37]

Figure 13.15-1 Appearance of roundworms that have been retrieved within the nasogastric reflux from a foal with an ascarid impaction. The large size of these ascarids (bar = 1 cm) contributes to the risk of impaction following sudden kills of these parasites by broad-spectrum anthelmintics.

13.15.2.2

ILEAL IMPACTION

Ileal impactions most commonly occur in adult horses in the southeastern United States. Although feeding of coastal Bermuda hay has been implicated in the regional distribution of the disease, separating geographic location from regional hay sources as risk factors has been difficult. Nonetheless, feeding coastal Bermuda hay likely places horses at risk of ileal impaction, particularly if the coarse fiber content of the hay is high. Furthermore, sudden changes in feed from an alternate type of hay to coastal Bermuda hay likely places a horse at risk of ileal impaction.[38] Studies in England have revealed tapeworm infection as another important risk factor for ileal impaction. Based on risk analysis, the data suggested that in excess of 80% of the ileal impaction cases studied were associated with serologic or fecal evidence of tapeworm infection.[39] Because of the poor sensitivity of fecal analysis for tapeworms, Proudman and Trees have developed a serologic test (enzyme-linked immunosorbent assay) with a sensitivity of approximately 70% and a specificity of 95%.[40]

Clinical signs of horses with ileal impaction are typical for a horse with small intestinal obstruction, including onset of moderate to severe colic and loops of distended small intestine palpable per rectum as the condition

progresses. Because the ileum is the distal most aspect of the small intestinal tract, nasogastric reflux may take a considerable time to develop and is found in approximately 50% of horses requiring surgical correction of impacted ileum.[35,41] One usually makes the diagnosis at surgery, although on occasion one may palpate an impacted ileum per rectum. Multiple loops of distended small intestine frequently make the impaction difficult to palpate. Ileal impactions may resolve with medical treatment[36] but frequently require surgical intervention (Figure 13.15-2). At surgery, one can infuse fluids directly into the mass, allowing the surgeon to breakdown the impaction. The surgeon may include dioctyl sodium sulfosuccinate in the infused fluid to aid in disruption of the mass. Extensive small intestinal distention and intraoperative manipulation of the ileum may lead to postoperative ileus,[42] but recent studies indicate that this complication is less frequent as the duration of disease before admission decreases.[35] Recent studies indicate that the prognosis for survival is good.[35,36] 925 926

Figure 13.15-2 Intraoperative view of an ileal impaction. The distended appearance of the ileum as it courses toward the cecal base is notable.

13.15.2.3 ILEAL HYPERTROPHY

Ileal hypertrophy is a disorder in which the muscular layers (circular and longitudinal) of the ileum hypertrophy for unknown reasons (idiopathic) or following an incomplete or functional obstruction. For idiopathic cases, proposed mechanisms include parasympathetic neural dysfunction resulting in chronically increased muscle tone and subsequent hypertrophy of the muscular layers of the ileal wall. Such neural dysfunction possibly could result from parasite migration. Alternative hypotheses include chronic increases in the muscular tone of the ileocecal valve, leading to muscular hypertrophy of the ileum as it contracts against a

partially occluded ileocecal valve. The jejunum also may be hypertrophied, alone or with the ileum. Clinical signs include chronic intermittent colic as the ileum hypertrophies and gradually narrows the lumen diameter. In one study, partial anorexia and chronic weight loss (1 to 6 months) were documented in 45% of the horses, most likely because of intermittent colic and reduced appetite. Because hypertrophy does not affect the ileal mucosa, no reason exists to believe that these horses experience malabsorption of nutrients. One usually makes the diagnosis at surgery, although one may palpate the hypertophied ileum per rectum in some cases. For treatment, one performs an ileocecal or jejunocecal anastomosis to bypass the hypertrophied ileum. Without surgical bypass, intermittent colic persists and the thickened ileum ultimately may rupture.[43] The prognosis is fair with surgical treatment.[44]

Secondary ileal hypertrophy is most commonly notable in horses that previously have had colic surgery and that may have a partial or functional obstruction at an anastomotic site. For example, in one case report, a horse developed ileal hypertrophy after surgical correction of an ileocecal intussusception.[45] Ileal hypertrophy also was noted in a horse with cecal impaction in which an ileocolic anastomosis was oriented incorrectly.[46] Horses are typically re-presented for recurrence of colic in these cases. Surgical therapy is directed at addressing the cause of small intestinal obstruction and resecting hypertrophied intestine.

13.15.2.4 MECKEL'S DIVERTICULUM

Meckel's diverticulum is an embryonic remnant of the vitelloumbilical duct, which fails to atrophy completely and becomes a blind pouch projecting from the antimesenteric border of the ileum.[47,48] However, similar diverticula also have been noted in the jejunum.[49] These diverticula may become impacted, resulting in partial luminal obstruction, or may wrap around an adjacent segment of intestine, causing strangulation.[47] Occasionally, an associated mesodiverticular band may course from the diverticulum to the umbilical remnant and serve as a point around which small intestine may become strangulated. Mesodiverticular bands also may originate from the embryonic ventral mesentery and attach to the antimesenteric surface of the bowel, thereby forming a potential space within which intestine may become entrapped. Clinical signs range from chronic colic for an impacted Meckel's diverticulum to acute severe colic for intestine strangulated by a mesodiverticular band. One makes the diagnosis at surgery, and treatment requires resection of the diverticulum and any associated bands. The prognosis is good for horses with simple impaction of a Meckel's diverticulum and is guarded for horses with an associated small intestinal strangulation.[50]

13.15.2.5 ADHESIONS

Adhesions of one segment of bowel to another or of a segment of intestine to other organs and the body wall most typically occur following abdominal surgery and may be clinically silent, cause chronic colic attributable to partial obstruction, or result in acute obstruction. These differing clinical syndromes are attributable to the type of adhesions that develop. For example, a fibrous adhesion that does not by itself obstruct the intestinal 926
lumen might serve as the pivot point for a volvulus, whereas an adhesion between adjacent segments of the 927
intestinal tract may create a hairpin turn that causes chronic partial obstruction.[51] The number of adhesions that develop also may vary greatly from horse to horse. Some horses may develop a single adhesion adjacent to an anastomotic site or a discrete segment of injured intestine, whereas other horses may develop diffuse adhesions involving multiple segments of intestine, likely because of widespread inflammation of the peritoneum at the time of the original surgery.

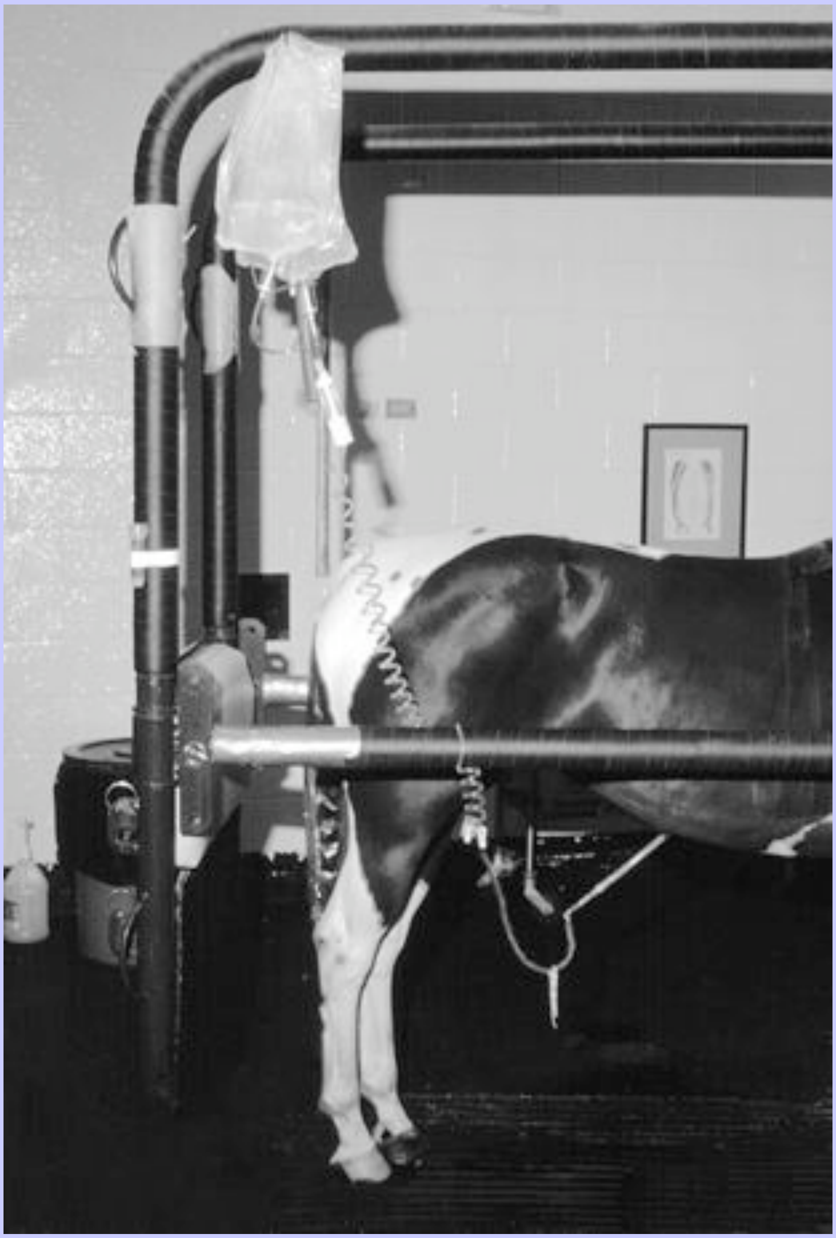
The mechanism whereby adhesions develop is complex but likely involves initial injury to the serosa initiated by intestinal ischemia, reperfusion injury, and luminal distention.[52] Importantly, such injury involves infiltration of neutrophils into the serosa accompanied by loss of mesothelial cells. In one study assessing the margins of resected small intestine, extensive neutrophil infiltration was documented in the serosa, particularly in the proximal resection margin that had been distended before correction of a variety of strangulating lesions.[53] Regions of serosal injury and inflammation subsequently undergo reparative events similar to any wound, including local production of fibrin, de novo synthesis of collagen by infiltrating fibroblasts, and ultimately maturation and remodeling of fibrous tissue. Unfortunately, during this process, fibrin may result in injured intestinal surfaces adhering to adjacent injured bowel or an adjacent organ. Once a fibrinous adhesion has developed, new collagen synthesis may result in a permanent fibrous adhesion. Alternatively, proteases released by local phagocytes may lyse fibrinous exudate, thereby reversing the adhesive process. Thus one can view formation of adhesions as an imbalance of fibrin deposition and fibrinolysis.[54]

Prevention of adhesions depends on inhibition of the mechanisms involved in adhesion formation, including reduction of serosal injury with early intervention and good surgical technique, reduction of inflammation by administration of antiinflammatory medications, physical separation of inflamed serosal surfaces (e.g., carboxymethylcellulose and hyaluronan),[55–57] and pharmacologic modulation of fibrinous adhesion formation (e.g., heparin).[58] In addition, early return of motility in the small intestine after surgery may reduce contact time between inflamed surfaces of intestine, thereby reducing the chances of adhesion formation.[54]

Horses at greatest risk of developing adhesions after colic surgery appear to be those that have small intestinal disease.[51,59] In one study of horses undergoing surgical correction of small intestinal obstruction, 22% developed a surgical lesion associated with adhesions. Foals appear to have an increased incidence of adhesions compared with mature horses regardless of the nature of the abdominal surgery.[51] One study indicated that 17% of foals developed lesions attributable to adhesions regardless of the type of initial surgery.[60] Studies conflict as to whether the degree of surgical intervention influences adhesion formation,[51] but in one study, horses that require enterotomy or resection and anastomosis were at greatest risk of developing adhesions.[59] As an indication of the importance of postoperative adhesion formation, adhesions were among the most common reasons for repeat laparotomy in postoperative colic patients.[59,61]

Clinical signs of horses with adhesions vary greatly depending on whether the adhesion is causing partial obstruction or complete luminal obstruction or involves intestinal vasculature. Adhesions would be an important differential diagnosis for intermittent colic in the postoperative period, particularly if such colic was not relieved by nasogastric decompression of the stomach. Continued intermittent colic should prompt abdominocentesis to determine if septic peritonitis is present, which may contribute to adhesion formation. Placement of a large bore drain and peritoneal lavage (Figure 13.15-3) aids resolution of peritonitis and may reduce adhesion formation by reducing intraabdominal inflammation. If postoperative colic persists, one may 927
elect repeat laparotomy or laparoscopy. In one study of adhesions, 70% of repeat laparotomies were performed 928
within 60 days, suggesting that surgical colic attributable to adhesions typically occurs within 2 months of an initial surgical procedure. Unfortunately, the prognosis for horses with colic attributable to adhesions is low, with only 16% of horses in one study surviving from adhesion-induced colic.[51]

Figure 13.15-3 Peritoneal lavage in a horse. The use of an intravenous administration set and a large-bore catheter placed in the dependent portion of the abdomen adjacent to the ventral midline incision is notable.



13.15.2.6

POSTOPERATIVE ILEUS

The definition of *ileus* is intestinal obstruction, including physical and functional obstructions. However, in veterinary medicine, the term typically is used to designate a lack of progressive aboral propulsion of ingesta resulting in functional obstruction.[62] One typically bases the diagnosis of postoperative ileus on the presence of excessive gastric fluid accumulation (reflected as excessive nasogastric reflux). Postoperative ileus may occur following any abdominal exploratory procedure. However, horses undergoing surgery for strangulating small intestinal lesions or small intestinal obstructive lesions such as an ileal impaction are at greatest risk.[42] Recently, the syndrome of postoperative ileus in horses has been broadened to include those horses that may have delayed transit of ingesta through the large intestine following surgery. This large intestinal ileus may follow any type of surgery, particularly horses that have had orthopedic surgery, and is characterized by reduced fecal output (fewer than three piles of manure per day) rather than excessive nasogastric reflux.[62] However, horses with excessive nasogastric reflux are unlikely to have normal fecal output, so the distinction between these two manifestations of ileus is not absolute.

Mechanisms involved in precipitating postoperative ileus characterized by small intestinal dysfunction likely involve local inflammation, reduced coordination of progressive motility, and increased sympathetic tone. A recent series of studies in the rat has shown that surgical manipulation of intestine results in delayed transit time associated with infiltration of neutrophils into intestinal longitudinal muscle[63–65] and upregulation of inducible nitric oxide synthase and COX-2. The mechanisms in the horse may be similar in that extensive manipulation of the intestine resulted in abnormal intestinal motility in ponies,[66] and prostanoids and nitric oxide alter or reduce intestinal motility in horses.[67–69]

Clinical signs of postoperative ileus following colic surgery include evidence of abdominal pain, increased heart rate, reduced gastrointestinal sounds, and reflux of gastric fluid via a nasogastric tube. Of these signs, heart rate is critical because it appears to be a more sensitive indicator of pain in the postoperative period than overt evidence of colic. Therefore a sudden increase in the heart rate of a postoperative patient following colic surgery should prompt immediate nasogastric intubation to decompress the stomach. Treatment should include attempts at obtaining reflux from the horse at frequent intervals rather than relying on passive flow of reflux. In addition, administration of intravenous fluids should account for the maintenance requirement (50 ml/kg/day, about 1 L/hr in the average horse) and fluid losses via reflux. In practice, this requires frequent monitoring of packed cell volume and total protein to ensure that the horse remains well hydrated. Although concerns have arisen that overhydrating horses may contribute to increased nasogastric reflux,[42] keeping horses well-hydrated to avoid hypovolemic shock is critical. Additionally, one should monitor electrolytes frequently, particularly considering their potential role in smooth muscle contraction and nerve excitability. Because of the important role of inflammation in postoperative ileus, including elaboration of COX-2–produced prostanoids,[70] administration of NSAIDs is indicated. NSAID administration is particularly necessary if postoperative ileus is associated with endotoxemia, because lipopolysaccharide-induced prostanoid production disrupts propulsive motility in horses.[71,72] Interestingly, phenylbutazone is more effective than flunixin meglumine at reducing the deleterious actions of lipopolysaccharide on intestinal motility.[73] However, one should use caution when administering NSAIDs to patients with postoperative ileus in light of research suggesting that complete inhibition of prostanoid production can alter motility patterns in normal equine intestine.[68] The advent of selective COX-2 inhibitors may provide optimal antiinflammatory treatment in the future.[74]

Other treatments aimed at specifically modulating intestinal motility include lidocaine (bolus of 1.3 mg/kg followed by 0.05 mg/kg/min for 24 hours), erythromycin (0.5 to 1.0 mg/kg slow intravenous infusion in 1 L saline every 6 hours), and metoclopramide (0.04 mg/kg/hr).[66,75,76] The mechanism of lidocaine is presumed to be inhibition of sensory nerve activity within the wall of the intestine, thereby reducing reflex sympathetic inhibitory activity. In addition, intravenously administered lidocaine appears to be an effective analgesic. Thus an important feature of intravenous lidocaine therapy may be to control postoperative pain-induced reduction of gastrointestinal motility and mucosal secretory activity.[77] Metoclopramide may stimulate intestinal motility by several mechanisms, including dopamine receptor blockade, cholinergic stimulation, and adrenergic blockade.[66] Although metoclopramide has been shown to be beneficial for reversing postoperative ileus in clinical patients and research animals, it has central nervous system excitatory side effects in the horse that make its use difficult. Nonetheless, administration of metoclopramide to horses with postoperative ileus 928
resulted in a significantly reduced duration of reflux and shorter postoperative hospital stays compared with 929
horses not receiving this drug.[76] In the same study, constant infusion of metoclopramide was superior to intermittent infusion. Recent in vitro studies indicate that metoclopramide effectively increases smooth muscle contractile activity throughout the small intestine. Similarly, the motilin agonist erythromycin had stimulatory effects on equine small intestine, although the results were not uniform throughout the small intestine. Erythromycin stimulates contractile activity in the longitudinal muscle of the pyloric antrum but inhibits contractile activity in circular smooth muscle in this segment of the gastrointestinal tract.[75] The latter may be attributable to activation of motilin receptors on inhibitory nerves and may result in enhanced gastric emptying. In vivo studies on erythromycin confirmed the stimulatory action of this drug on the distal small intestine and indicated this drug also stimulates contractile activity in the cecum and pelvic flexure. However, the stimulation depends on the temporal association with surgery. Erythromycin stimulated contractile activity in the postoperative period in the ileum and pelvic flexure but not the cecum,[78] suggesting this drug may be useful for treating select cases of postoperative ileus.

For horses with presumed ileus of the large colon, signs included reduced fecal output (fewer than three piles of manure per day), reduced gastrointestinal sounds, variable presence of colic, and on occasion a palpable impaction of the cecum or large colon. Risk factors for this syndrome include orthopedic surgery, length of the operative period, and most importantly inadequate treatment with phenylbutazone, presumably resulting from insufficient control of postoperative pain. Although treatment of large colon impaction in the postoperative period typically is uncomplicated, onset of cecal impaction is fatal in many cases because of the difficulty in recognizing horses that have cecal dysfunction. Therefore one should pay close attention to fecal production and optimal analgesic treatment in any horse following an orthopedic procedure.[62] Other painful procedures, including ophthalmologic procedures, also likely place horses at risk of developing ileus of the large intestine.

13.15.3 Large Intestinal Simple Obstruction

Simple obstructions of the large intestine such as impaction tend to have a more gradual onset than those of the small intestine, although horses may become acutely and severely painful with some forms of colon displacement. In fact, some of these cases mimic and may progress toward large colon volvulus. Medical therapy is frequently successful in correcting large colon impactions. However, cecal impactions present much more of a dilemma because of the greater propensity of this organ to rupture, the relative difficulty of surgically manipulating the cecum, and the onset of cecal dysfunction that may prevent the cecum from emptying following surgical resolution of impaction.

13.15.3.1 CECAL IMPACTION

Cecal impaction may be divided into two syndromes: primary cecal impactions that result from excessive accumulation of ingesta in the cecum and secondary cecal impactions that develop while a horse is being treated for a separate problem.[79,80] Although primary impactions typically consist of impacted, relatively dry fecal material and secondary cecal impactions tend to have fluid contents, considerable overlap exists between the two syndromes, and one must approach each case carefully. In horses with primary cecal impactions, onset of abdominal pain occurs over a number of days, reminiscent of the development of a large colon impaction. One should differentiate cecal impactions from large colon impactions on the basis of rectal palpation findings. Cecal impactions have a propensity to rupture before the development of severe abdominal pain or systemic deterioration and therefore must be monitored closely.[79] Secondary cecal impactions typically develop following unrelated surgical procedures that result in postoperative pain (particularly orthopedic surgeries). Secondary cecal impactions may be even more difficult to detect because one may attribute postoperative depression and decreased fecal output to the operative procedure rather than to colic. By the time horses with secondary cecal impactions show noticeable signs of colic, the cecum may be close to rupture. In many cases, no signs of impending rupture are evident.[80] Therefore all horses that undergo surgeries in which considerable postoperative pain may develop should have feed intake and manure production closely monitored. A recent study indicated that horses that produce fewer than three piles of manure daily in the postoperative period are at risk of developing a large intestinal impaction. Furthermore, horses that underwent prolonged (>1 hour) orthopedic surgery that received inadequate treatment with phenylbutazone were at considerable risk of reduced postoperative fecal output.[62] These results are in contrast to statements indicating that NSAIDs may place horses at risk of impaction, statements that appear to be based largely on clinical impressions rather than on risk analysis.[80]

The diagnosis of primary cecal impaction is based on palpation of a firm, impacted cecum per rectum. In some cases, cecal impactions may be difficult to differentiate from large colon impactions. However, careful palpation reveals the inability to move the hand completely dorsal to the impacted viscus because of the 929
attachment of the cecum to the dorsal body wall. Treatment for horses with primary cecal impactions may 930
include initial medical therapy, including aggressive administration of intravenous fluids and judicious use of analgesics.[80] However, if the cecum is distended grossly or if medical therapy hasno effect within a reasonable period of time, surgical evacuation of the cecum via a typhlotomy is indicated.[79] In addition, performing an ileocolostomy to bypass the cecum is advisable, because postoperative cecal motility dysfunction with recurrence of the impaction is common.[46,81]

In horses that develop secondary cecal impactions, diagnosis is based on palpation of a greatly distended cecum filled with semifluid intestinal contents. The nature of the contents likely is related to the more rapid progression of this disease compared with primary cecal impaction. One should not delay surgery because of the risk of cecal rupture.[82] However, if the cecum appears healthy following typhlotomy and evacuation, bypass of the cecum is not as critical as it is for primary impactions as long as one can control the inciting cause of the impaction (such as orthopedic pain).

The prognosis is guarded for surgical treatment of all cecal impactions because of the potential for the cecum to rupture during prolonged medical treatment or during surgical manipulation, the possibility of abdominal contamination during surgery, and the extensive surgical procedures required. In a recent report, seven of nine horses for which cecal impaction was treated by typhlotomy and ileocolostomy or jejunocolostomy lived long

term.[46] However, a separate report indicated that all horses with cecal impaction following another disease process had cecal rupture without any signs of impending rupture.[80]

13.15.3.2

LARGE COLON IMPACTION

Ingesta impactions of the large colon occur at sites of anatomic reductions in luminal diameter, particularly the pelvic flexure and the right dorsal colon.[83] Although a number of risk factors have been reported, most have not been proved. However, a sudden restriction in exercise associated with musculoskeletal injury appears frequently to be associated with onset of impaction.[84] Another consideration is equine feeding regimens, which usually entail twice daily feeding of concentrate. Such regimens are associated with large fluxes of fluid into and out of the colon, associated with readily fermentable carbohydrate in the colon and subsequent increases in serum aldosterone, respectively. One may prevent these fluid fluxes, which may cause dehydration of ingesta during aldosterone-stimulated net fluid flux out of the colon, with frequent small feedings.[32]

Amitraz, an acaricide associated with clinical cases of colon impaction, can induce impaction of the ascending colon.[85,86] This effect may provide some clues as to the pathogenesis of large colon impaction. In particular, amitraz appears to alter pelvic flexure pacemaker activity, resulting in uncoordinated motility patterns between the left ventral and left dorsal colon and excessive retention of ingesta. Absorption of water from the ingesta increases with retention time, dehydrates the contents of the colon, and results in impaction. Conceivably, parasite migration in the region of a pacemaker may have a similar action.[87] Other factors implicated in large colon impaction include limited exercise, poor dentition, coarse roughage, or dehydration.

Clinical signs of large colon impaction include slow onset of mild to moderate colic. Fecal production decreases, and the feces are often hard, dry, and mucus-covered because of delayed transit time. The heart rate may be elevated mildly during episodes of pain but is often normal. Signs of abdominal pain are typically well controlled with administration of analgesics but become increasingly more severe and refractory if the impaction does not resolve. The diagnosis is based on palpation of a firm mass in the large colon per rectum. However, one may underestimate the extent of the impaction by rectal palpation alone because much of the colon is out of reach. Adjacent colon may be distended if the impaction has resulted in complete obstruction. One should attempt initial medical treatment. Administration of analgesics (e.g., flunixin meglumine at 0.5 to 1.1 mg/kg intravenously every 8 to 12 hours; butorphanol at 0.04 to 0.1 mg/kg intramuscularly every 4 to 6 hours; or xylazine at 0.3 to 0.5 mg/kg intravenously as needed) controls intermittent abdominal pain. Administration of oral laxatives such as mineral oil (2 to 4 L by nasogastric tube every 12 to 24 hours) and the anionic surfactant dioctyl sodium sulfosuccinate (6 to 12 g/500 kg diluted in 2 to 4 L of water by nasogastric tube every 12 to 24 hours) are used commonly to soften the impaction. Saline cathartics such as magnesium sulfate (0.1 mg/kg in 2 to 4 L by nasogastric tube) also may be useful. One should not permit access to feed. For impactions that persist, one should institute aggressive oral and intravenous fluid therapy (2 to 4 times the maintenance fluid requirement). If the impaction remains unresolved, the horse becomes uncontrollably painful, or extensive gas distention of the colon occurs, surgery is indicated. In addition, one can monitor abdominal fluid serially to determine the onset of intestinal compromise.[83] At surgery, one evacuates the contents of the colon via a pelvic flexure enterotomy. The prognosis is good for those horses in which impactions resolve medically (95% long-term survival in one study) and fair in horses that require surgical intervention (58% long-term survival in the same study).[84]

13.15.3.3 ENTEROLITHS

Enteroliths are mineralized masses typically composed of magnesium ammonium phosphate (struvite).[88] 930
However, magnesium vivianite also has been identified in enteroliths, along with variable quantities of 931
sodium, sulfur, potassium, and calcium. The formation of magnesium-based minerals is puzzling because of the relative abundance of calcium in colonic fluids, which would favor the formation of calcium phosphates (apatite) rather than struvite.[89] However, elevated dietary intake of magnesium and protein may play a role. Many horses that develop enteroliths are located in California and are fed a diet consisting mainly of alfalfa hay. Analysis of this hay has revealed a concentration of magnesium approximately 6 times the daily requirements of the horse.[90] Furthermore, the high protein concentration in alfalfa hay may contribute to calculi formation by increasing the ammonia nitrogen load in the large intestine. Enteroliths most commonly form around a nucleus of silicon dioxide (a flintlike stone), but nidi have included ingested nails, rope, and hair.[88] Enteroliths usually are found in the right dorsal and transverse colons.[90] Although enterolithiasis has a wide geographic distribution, horses in California have the highest incidence. In one California study, horses with enterolithiasis represented 28% of the surgical colic population, and Arabians, Morgans, American Saddlebreds, and donkeys were at greatest risk of this disease.[91] In a study of enterolithiasis in Texas, risk factors also included feeding of alfalfa hay and Arabian breed. However, in that study, miniature horses were also at risk.[92] Horses with enteroliths are rarely under 4 years old,[90] although an enterolith in an 11-month-old miniature horse has been reported recently.[93]

Enterolithiasis is characterized by episodic, mild to moderate, intermittent abdominal pain.[90] Progressive anorexia and depression may develop. The amount of pain depends on the degree of obstruction and amount of distention. Partial luminal obstruction allows the passage of scant, pasty feces. Heart rate varies and depends on the degree of pain. In some cases, an enterolith is forced into the small colon, where it causes acute small colon obstruction. One may diagnose enteroliths by abdominal radiography or at surgery. On rare occasions, one may palpate an enterolith per rectum, particularly if it is present in the distal small colon.

In general, these cases require surgery, although enteroliths being retrieved per rectum have been reported. In fact in one study, 14% of horses presented for treatment of enterolithiasis had a history of passing an enterolith in the feces. However, enteroliths typically are located in the right dorsal colon, transverse colon, or small colon. At surgery, one gently pushes the enterolith toward a pelvic flexure enterotomy, but removal frequently requires a separate right dorsal colon enterotomy to prevent rupture of the colon. Following removal of an enterolith, one must conduct further exploration to determine if other enteroliths are present. Solitary enteroliths are usually round, whereas multiple enteroliths have flat sides. The prognosis is good (92% 1-year survival in one study of 900 cases), unless the colon ruptures during removal of an enterolith. In one recent study, rupture occurred in 15% of cases.[91]

13.15.3.4 SAND IMPACTIONS OF THE LARGE COLON

Sand impactions are common in horses with access to sandy soils, particularly horses eating feed placed on the ground. Some horses, especially foals, deliberately eat sand. Fine sand tends to accumulate in the ventral colon, whereas coarse sand may accumulate in the dorsal colon.[94,95] However, individual differences in colonic function may contribute to accumulation of sand, because some horses can clear consumed sand, whereas others cannot. Distention from the impaction itself, or gas proximal to the impaction, causes

abdominal pain. In addition, sand may trigger diarrhea, presumably because of irritation of the colonic mucosa.[96] In horses with sand impactions, clinical signs are similar to those of horses with large colon impactions.[94] One may find sand in the feces, and auscultation of the ventral abdomen may reveal sounds of sand moving within the large colon.[97] However, unlike sand-induced diarrhea, one may not hear sand impactions easily because of the lack of colonic motility. To determine the presence of fecal sand, one places several fecal balls in a rectal palpation sleeve or other container, which subsequently is filled with water. If sand is present, it accumulates at the bottom of the container. In addition, one may detect mineral opacity within the colon on abdominal radiographs, particularly in foals, ponies, and small horses. Abdominal paracentesis typically yields normal fluid and poses some risk because large quantities of sand in the ventral colon make inadvertent perforation of the colon more likely.[95] Peritoneal fluid is often normal but may have an elevated protein concentration.

Initially, medical therapy is warranted. Administration of psyllium hydrophilic mucilloid (0.25 to 0.5 kg/500 kg in 4 to 8 L of water by stomach tube) may facilitate passage of sand. One should administer the solution rapidly because it will form a viscous gel. An alternative method of administration is to mix psyllium with 2 L of mineral oil, which will not form a gel and can be pumped through a nasogastric tube easily. One then pumps 2 to 4 L of water through the tube. The psyllium separates from the oil phase and mixes with the water, forming a gel within the gastrointestinal tract. Psyllium is thought to act by stimulating motility or by agglutinating the sand. However, a recent experimental study failed to show a benefit of this treatment for clearing sand from the colons of otherwise normal horses.[98] If a severe impaction is present, one should not 931
give the psyllium until softening the impaction by administrating intravenous or oral fluids and other laxatives. 932
Perforation is a potential complication in horses with sand impactions because the sand stretches and irritates the intestinal wall and causes inflammation. Therefore if colic becomes intractable, one should perform surgical evacuation of the large colon. The prognosis is generally good.[94,95]

13.15.3.5 LARGE COLON DISPLACEMENT

Displacement of the ascending colon is a common cause of large intestinal obstruction. The ascending colon is freely movable except for the right dorsal and ventral colons. Contact with adjacent viscera and the abdominal wall tends to inhibit movement of the ascending colon from a normal position; however, accumulation of gas and fluid or ingesta may cause the colon to migrate.[99] Feeding practices, including feeding of large concentrate meals, likely plays a role in initiating displacement of the large colon. Large concentrate meals increase the rate of passage of ingesta, allowing a greater percentage of soluble carbohydrates to reach the large intestine,[31] which in turn increases the rate of fermentation and the amount of gas and volatile fatty acids produced. The production of large amounts of volatile fatty acids stimulates the secretion of large volumes of fluid into the colon.[100] The association between feeding concentrate and development of displacements of the large colon is illustrated by studies indicating that ascending colon displacement is more prevalent in horses fed a high-concentrate, low-roughage diet.[101] Abnormal motility patterns of the ascending colon also have been suggested to contribute to the development of colonic displacement. Feeding stimulates colonic motility via the gastrocolic reflex, but large meals may alter normal motility patterns and concurrently allow rapid accumulation of gas and fluid from fermentation.[31,102] Migration of parasite larvae (strongyles) through the intestinal wall also has been shown to alter colonic motility patterns. Other experimental studies also have shown that *Strongylus vulgaris* infection results in reduced blood flow to segments of the large intestine without necessarily causing infarction. Electric activity of the colon and cecocolic junction increases after

infection with *S. vulgaris* and cyathostome larvae, probably reflecting a direct effect of migration through the intestine and an early response to reduced blood flow.[103]

Displacements of the ascending colon generally are divided into three types: left dorsal displacement, right dorsal displacement, and retroflexion. Left dorsal displacement is characterized by entrapment of the ascending colon in the renosplenic space. The colon often is twisted 180 degrees such that the left ventral colon is situated in a dorsal position relative to the left dorsal colon. The entrapped portion may be only the pelvic flexure or may involve a large portion of the ascending colon, with the pelvic flexure situated near the diaphragm. The colon may become entrapped by migrating dorsally between the left abdominal wall and the spleen or may migrate in a caudodorsal direction over the nephrosplenic ligament. Occasionally, one can palpate the ascending colon between the spleen and abdominal wall, lending support to the first mechanism of displacement. Gastric distention is thought to predispose horses to left dorsal displacement of the ascending colon by displacing the spleen medially, allowing the colon room to migrate along the abdominal wall. Right dorsal displacement begins by movement of the colon cranially, medial (medial flexion) or lateral (lateral flexion) to the cecum. According to one author, the proportion of right dorsal displacements with medial versus lateral flexion is approximately 1:15.[104] In either case the pelvic flexure ends up adjacent to the diaphragm. Retroflexion of the ascending colon occurs by movement of the pelvic flexure cranially without movement of the sternal or diaphragmatic flexures.

Displacement of the ascending colon partially obstructs the lumen, resulting in accumulation of gas or ingesta and causing distention. Secretion of fluid in response may exacerbate the distention.[105] Tension and stretch of the visceral wall is an important source of the pain associated with colonic displacement. Tension on mesenteric attachments and the root of the mesentery by the enlarged colon also may cause pain.[99] Ischemia rarely is associated with nonstrangulating displacement of the colon. However, vascular congestion and edema often occur in the displaced segments of colon, resulting from increased hydrostatic pressure from reduced venous outflow. Morphologic damage to the tissues is usually minor.

Clinically, displacement of the ascending colon is characterized by intermittent signs of mild to moderate abdominal pain of acute onset. However, one also may note an insidious onset of colic.[104] One may note dehydration if the duration of the displacement is prolonged. The heart rate may be elevated during periods of abdominal pain but is often normal. Abdominal distention may be present if the colon is enlarged by gas, fluid, or ingesta. Fecal production is reduced because progressive motility of the large intestine is absent. One often diagnoses left dorsal displacements by palpation per rectum. One can feel the left ventral colon in a dorsal position; it often is filled with gas. One can trace the ascending colon to the nephrosplenic space, and the spleen may be displaced medially. Alternatively, one can reach a tentative diagnosis using abdominal ultrasonography. The spleen is visible on the left side of the abdomen, but the gas-distended bowel obscures the left kidney. Evaluation of this technique indicates that false positives occur in few instances, although false 932
negatives occasionally may occur.[106] A definitive diagnosis therefore may require surgery. Right dorsal 933
displacements are characterized by the presence of the distended ventral colon running across the pelvic inlet and may be felt between the cecum and the body wall if a lateral flexion is present. The pelvic flexure is usually not palpable. Retroflexion of the ascending colon may produce a palpable kink in the colon. If the displaced colons are not distended by gas in the instance of right dorsal displacement and retroflexion, the ascending colon may not be palpable and is conspicuous by its absence from a normal position. Peritoneal fluid may increase in amount, but the color, protein concentration, and white blood cell count are usually normal. However, as the displaced segment becomes edematous, fluid leaking through the serosa into the peritoneal fluid increases the protein concentration.

Surgical correction of colon displacement is the most effective means of resolving this disorder. However, nonsurgical intervention has been successful in select cases of nephrosplenic entrapment of the large colon.[106–108] Before attempting such manipulations, the clinician must be certain of a diagnosis. One anesthetizes the horse and places it in right lateral recumbency, rotates the horse up to dorsal recumbency, rocking it back and forth for 5 to 10 minutes, and then rolls the horse down into left lateral recumbency.[109] One should palpate the nephrosplenic space per rectum to determine whether the entrapment has been relieved before recovering the horse from anesthesia. One may administer phenylephrine (3–6 μg/kg/min over 15 minutes) to decrease the size of the spleen.[110] More recently, phenylephrine has been used successfully with 30 to 45 minutes of exercise to reduce nephrosplenic entrapments in four of six horses.[26] The authors suggested that the technique be used on horses with mild to moderate colonic distention, particularly when financial constraints are severe. A number of cases occur in which nonsurgical interventions do not correct the problem and others in which nonsurgical manipulations correct the entrapment but result in large colon volvulus or displacement.[111] One should take horses in such condition to surgery promptly. The prognosis for horses with large colon displacement is good. In one study on horses with nephrosplenic entrapment of the large colon, survival exceeded 90%.[108]

13.15.3.6 FOREIGN BODY AND FECALITH OBSTRUCTION

The horse, particularly young horses, may ingest foreign material that can cause obstruction, such as bedding, rope, plastic, fence material, and feedbags. These foreign bodies may result in impaction with ingesta and distention of the intestine, typically in the transverse or descending colon. Young horses usually are affected. In one study the obstructing mass could be palpated per rectum in three of six horses.[112]

Figure 13.15-4 Intramural hematoma of unknown origin in the small colon of a horse taken to surgery for persistent signs of colic. The lack of a complete physical obstruction suggested a functional obstruction at the site of the hematoma.

Fecaliths are common in ponies, miniature horses, and foals.[113] Older horses with poor dentition also may be predisposed to fecaliths because of the inability to masticate fibrous feed material fully. Fecaliths commonly cause obstruction in the descending colon and may cause tenesmus.[112] Other clinical signs are similar to those of enterolithiasis. Abdominal radiography may be useful in smaller patients to identify the obstruction, especially if gas distention around the foreign body or fecalith provides contrast. The horse usually requires surgical treatment.

13.15.3.7 MURAL MASSES AND STRICTURES

Mural masses such as abscesses, tumors (adenocarcinoma, lymphosarcoma), granulomata, and hematomas (Figure 13.15-4) can cause luminal obstruction and impaction, typically in older horses. Impaction may result from obstruction of the lumen or impaired motility in the segment of intestine with the mass. Abscesses may originate from the lumen of the intestine or may extend from the mesentery or mesenteric lymph nodes. Intramural hematomas form most commonly in the descending colon and cause acute abdominal pain.[114] Once the acute pain from the hematoma subsides, impaction proximal to the hematoma develops because of impaired motility through the affected portion of the colon. Trauma, ulceration of the mucosa, and parasitic damage are speculated causes of intramural hematomas.[114,115] Stricture of the large intestine occurs when fibrous tissue forms in a circular pattern around or within the intestine, reducing the luminal diameter and the 933
ability of the wall to stretch. Strictures may be congenital or may follow peritonitis, previous abdominal 934
surgery, or inflammatory bowel disease. In a report of 11 horses with inflammatory bowel disease, 6 horses had strictures, four of which were in the small intestine and two of which were in the large colon.[116]

Clinical signs vary according to the degree of luminal obstruction. Partial obstruction and impaction tend to produce mild to moderate abdominal pain of insidious onset. Mural hematomas tend to produce signs of acute abdominal pain.[114,115] Per rectal palpation of the abdomen may reveal the presence of a mass or simply the impacted segment but not the mass itself. One may note fever, weight loss, and anorexia if an abscess or tumor is the cause. An elevated white blood cell count; hyperfibrinogenemia; hyperglobulinemia; or normocytic, normochromic anemia may occur with abscesses or tumors. Peritoneal fluid may reflect the cause of the mass. Tumor cells may occur infrequently. One may note evidence of inflammation with bacteria if the cause of colic is an abscess or granuloma, in which case one should culture the fluid. Hematomas may cause hemorrhage into the peritoneal fluid. Treatment usually requires surgical resection of the mass. One may treat abscesses with appropriate antibiotics if the impaction can be resolved medically with oral or intravenous analgesics and laxatives. *Streptococcus* spp, *Actinomyces pyogenes, Corynebacterium pseudotuberculosis, Rhodococcus equi,* anaerobic bacteria, and gram-negative enteric organisms commonly are involved in abscesses.

13.15.3.8 ATRESIA COLI

Atresia of a segment of the colon is a rare congenital abnormality in horses. The heritability and causes of the condition are unknown. One potential mechanism for development of the lesion is intestinal ischemia during fetal life, which results in necrosis of a segment of intestine. Clinical signs include a failure to pass meconium and colic within the first 12 to 24 hours of life. Secondary abdominal distention results from complete intestinal obstruction, and abdominal radiographs may reveal gas-distended colon. One makes the diagnosis at surgery. Any portion of the colon may be absent, but the distal segment of the large colon or the proximal small colon usually is affected most severely. If sufficient tissue is present, one may attempt anastomosis to

the proximal blind end of the colon.[117] The prognosis depends on which segment of the colon is absent but is usually poor because of an absence of distal colon.

13.16—Neoplasia of the Alimentary Tract

Dana N. Zimmel

936

937

Neoplasia in the alimentary tract of the horse is uncommon.[1] Primary and metastatic neoplasia can affect multiple locations within the oral cavity and gastrointestinal tract (Boxes 13.16-1 and 13.16-2). Neoplasia is not limited to older horses. The average age of horses with squamous cell carcinoma is 8.6 to 14.6 years.[2,3] The alimentary form

of lymphoma occurs most commonly in horses less than 5 years of age.[4] Identification of benign versus malignant tumors is imperative to justify treatment and predict survival.

13.16.1 Clinical Signs

Clinical signs associated with alimentary neoplasia are related to the tumor location. Clinical signs of oral neoplasia can include enlargement or ulceration of the mandible or maxilla.[48] Neoplasia of the tongue results in weight loss, quidding, prepharyngeal dysphagia, halitosis, and nasal discharge containing feed material if the oropharynx is involved.[6–8] Tumors of the esophagus cause signs typical of esophageal dysphagia, ptyalism, choke, intermittent colic, fever, weight loss, and halitosis.[10,49,50] Gastric neoplasia can be associated with abnormal chewing and swallowing behavior, anorexia, weight loss, chronic intermittent colic, abdominal distention, and intermittent fever.[16] Abdominal neoplasia has been implicated in 4% of horses with intermittent or chronic colic.[51,52] Altered stool character, weight loss, ventral edema, and recurrent fever have been associated with intestinal neoplasia.[4] Acute signs of abdominal discomfort can occur in intestinal obstructions from malignant and benign neoplastic disease.

Paraneoplastic syndromes may occur in the horse. The most common syndromes are cancer cachexia, ectopic hormone production, anemia, leukocytosis, thrombocytopenia, hypergammaglobulinemia, fever, and neurologic abnormalities.[53] Horses with cancer cachexia have profound weight loss despite adequate consumption of calories.

13.16.2 Diagnostic Evaluation

Diagnosis of alimentary neoplasia can be challenging. Data collected from a complete blood count, biochemistry panel, and urinalysis may support the diagnosis of neoplasia but rarely confirms it. Normocytic normochromic anemia indicates chronic disease and is the most likely cause of anemia associated with neoplasia. Blood loss anemia (via gastrointestinal tract) and immune-mediated hemolytic anemia (lymphoma)[54] are less frequent causes of anemia associated with abdominal neoplasia. Peripheral eosinophilia has been reported in association with multisystemic eosinophilic, epitheliotropic disease with lymphoma.[14] Leukocytosis and hyperfibrinogenemia are common findings.

Serum chemistry can confirm hypoalbuminemia caused by inflammation of the bowel wall. Hyperglobulinemia can be characterized with serum electrophoresis, which is nonspecific and can reveal chronic inflammation. A few cases of lymphoma have been identified with monoclonal hypergammaglobulinemia.[55] Ectopic hormone production may result in hypercalcemia (calcium >14 mg/dl), which is associated with alimentary neoplasia such as lymphoma, multiple myeloma, carcinomata, and ameloblastoma.[2,56] Hypoglycemia (blood glucose <70 mg/dl) can occur with neoplasia of the pancreas or liver.[2]

Rectal examination may detect an abdominal mass, thickening of the intestinal wall, lymph node enlargement, or a gritty texture in horses with carcinomatosis.[2] Rectal biopsy can reveal lymphoma in some cases.[42] Fecal occult blood test is nonspecific for neoplastic disease but can reveal blood loss through the gastrointestinal tract. Occasionally, abdominocentesis can identify neoplasia if the tumor exfoliates cells into the abdomen. One can diagnose squamous cell carcinoma, adenocarcinoma, and mesothelioma from peritoneal fluid.[10,45,46,57] Characterization of peritoneal fluid as an inflammatory exudate or modified transudate without any neoplastic cells present is common. Cytologic analysis of peritoneal fluid samples collected by abdominocentesis accurately

predicted the presence of neoplasia in 11 of 25 cases in one study.[58] Cytologic examination of two or more peritoneal fluid samples increases the sensitivity of this test for detecting abdominal neoplasia. Measurement of peritoneal fluid glucose concentration and pH is valuable to differentiate inflammation in the peritoneum caused by neoplasia from bacterial peritonitis. Abdominal neoplasia typically is associated with peritoneal glucose concentrations similar to blood and pH higher than 7.3. d-xylose absorption tests can reveal malabsorptive diseases that include lymphoma.[42,59]

Immunoglobulin M deficiency is associated with lymphoma in some young adult horses, but the prevalence of immunoglobulin M deficiency in horses with lymphoma and the value of measuring serum immunoglobulin M concentrations for the diagnosis of lymphoma have not been evaluated.[60] DNA cell cycle analysis of suspect 937
neoplastic cells has been used to detect lymphoma in equine patients confirmed with the disease. This method of 938
evaluating fluid or tissues aspirates may increase the accuracy for diagnosing neoplasia in the future.[61]

13.16.2.1 BOX 13.16-1 NEOPLASIA OF THE ORAL CAVITY

Paraneoplastic bullous stomatitis[9]

A complete evaluation of the oral cavity may include using a full-mouth speculum, radiographs, and endoscopy of the pharynx. Evaluation of the esophagus and stomach with a 3-m endoscope can reveal intralumenal masses.[11] Pleuroscopy has been used to obtain biopsy samples of extralumenal masses surrounding the esophagus.[49] Contrast radiography can assist in the diagnosis of neoplasia within the wall or outside of the esophagus.[49,62] Ultrasonography of the stomach, small intestine, cecum, and large colon is useful in detecting intestinal wall thickness, abdominal masses, and excessive peritoneal fluid.[63] Identification of neoplasia in the liver, kidney or spleen may support metastasis to other parts of the gastrointestinal tract or lymph nodes. Laparoscopy and exploratory laparotomy often are required to obtain a final diagnosis.[64]

13.16.3 Specific Neoplasia

13.16.3.1 LYMPHOMA (LYMPHOSARCOMA)

Lymphoma is the most common neoplasia in the horse and has been divided into four categories. This section covers only the intestinal/alimentary form. In the past, lymphoma has been called lymphosarcoma, but the preferred term by oncologists is *lymphoma* because no benign form of this disease exists.[2] Lymphoma originates from lymphoid tissue and predominantly affects the small intestine and intestinal lymph nodes. Chronic weight loss from malabsorption, intermittent colic, and fever are the most common clinical findings.[27,65] Chronic diarrhea has been reported in some cases.[66] Paraneoplastic pruritus and alopecia have been identified in one case of diffuse lymphoma.[67] One generally does not note peripheral lymphadenopathy, but one may palpate enlargement of the intestinal lymph nodes on rectal examination.[4] Large colon resection for treatment of lymphoma in horses has increased short-term survival in two horses.[35] Chemotherapy in two mares that were pregnant extended their lives long enough to foal normally.[68] Long-term prognosis for intestinal lymphoma is poor.

13.16.3.2 SQUAMOUS CELL CARCINOMA

Squamous cell carcinoma (SCC) is a malignant tumor of the gastrointestinal epithelium. SCC is the second most common neoplasia in the horse and is the most common oral neoplasia. However, the incidence of SCC is rare.[10,16,50] In the oral cavity SCC may affect the lips, tongue, hard palate, pharynx, and mucosa.[69,70] Treatment for SCC in the oral cavity may involve surgical resection, iridium-192 brachytherapy, 5-fluorouracil, or intralesional cisplatin.[5,71–73] The prognosis for survival is good if complete removal of the tumor is possible. Metastasis beyond the regional lymph nodes is rare for oral SCC.

Squamous cell carcinoma is the most common tumor of the stomach and esophagus[11,16] and can invade these areas and metastasize to the lymph nodes and lungs. Abnormal masses were palpated on rectal examination in four of five cases of gastric SCC.[16] Treatment by surgical resection is not possible in most cases and the horses die or are euthanized.[2]

13.16.3.3 ADENOCARCINOMA

Adenocarcinoma is a malignant tumor that can occur in the small intestine, cecum, and large colon.[18] The tumor arises from the glandular crypts of the gastrointestinal tract and has been reported in middle-aged and older horses. Metastasis to the lymph nodes, liver, and lungs can occur. Intestinal adenocarcinoma has been reported to metastasize to the bone and was diagnosed using nuclear scintigraphy following injection of technetium-99m hydroxymethylene diphosphate.[29,32] No reports of successful surgical resection have been published.

13.16.3.4 LEIOMYOSARCOMA

Leiomyosarcoma is a malignant tumor of the smooth muscle lining the gastrointestinal tract and has been reported in the stomach, small intestine, and rectum.[13,22,23,40,58] In one case report, gastroscopy could not identify the mural mass in the stomach that was found during exploratory surgery. Another report describes a favorable outcome for surgical resection of a leiomyosarcoma that was protruding from the anal sphincter in a 4-year-old Quarter Horse.[40] Prognosis for survival is favorable if surgical resection is possible.

13.16.3.5 LEIOMYOMA

Leiomyoma is a benign tumor of the smooth muscle of the gastrointestinal tract that can occur in the stomach, small intestine, and small colon.[37,38] Clinical signs are consistent with intestinal obstruction. Surgical resection and anastomosis of the affected portion of the intestine have been performed without complications.

13.16.3.6 LIPOMA

Lipoma is a benign tumor that occurs in older horses (10 to 26 years) and arises from mesenteric adipocytes. The tumor grows on a stalk that wraps around the intestine, causing a strangulating lesion manifested clinically by acute obstructive colic. Intestinal injury caused by pedunculated lipomata may occur in the small intestine, small colon, and rectum. Long-term survival with surgical resection and anastomosis of the affected segment has been reported to be 40% to 50%.[26,74]

13.16.3.7 ORAL NEOPLASIA

Oral cavity neoplasia may involve the dental tissue (odontogenic tumors), bone (osteogenic tumors), or soft tissues (see Box 13.16-1). Ameloblastoma occurs in horses greater than 10 years old and mainly affects the mandible. Ameloblastic odontoma affects younger horses and usually involves the maxilla. Both are benign but locally invasive. Radiographs may distinguish the difference between an ameloblastoma (radiolucent lesion) and ameloblastic odontoma (radiolucent lesion with partially mineralized density). The best treatment option is surgical resection and radiation therapy regardless of the type.[48]

Juvenile mandibular ossifying fibroma occurs in the rostral mandible of young horses between the ages of 2 months and 2 years. The fibroma may cause significant distortion of the bone. With early diagnosis and surgical excision of the mass, the horse has a good prognosis.[75]

939

Melanomas, sarcoids, and oral papilloma occur on the mouth and lips. Melanomas rarely metastasize, but they commonly are found in the parotid salivary glands and lymph nodes. Sarcoids are the most common skin tumor that can involve the mouth. Ulcerations of the buccal mucosa are difficult to treat. Intralesional cisplatin, cryosurgery, radiation, and laser excision have been tried with limited success.[5] Equine papilloma virus is responsible for the common skin wart found on the lips and muzzle of young horses. These lesions are usually self-limiting but may be removed successfully by cryosurgery or excision.

13.17—Peritonitis

Charles Dickinson

13.17.1

Structure and Function

A number of detailed and informative reviews are available describing the anatomy, physiology, and pathophysiology of the equine peritoneum.[1–5] The peritoneum consists of a single layer of mesothelial cells lining the peritoneal cavity and serosal surfaces of the intraabdominal viscera. The mesothelial lining of the diaphragm, abdominal walls, and pelvic cavity is termed *parietal peritoneum*. The visceral peritoneum includes

the serosal surfaces of the intraabdominal organs. The parietal and visceral portions of the peritoneum are contiguous with each other through the omentum, mesenteries, and ligaments. Caudally, the peritoneum reflects over the surfaces of the pelvic organs (portions of the urogenital tract and rectum), excluding them from the peritoneal space, and thus much of the pelvic cavity and contents are described as retroperitoneal. The peritoneal space communicates with the lumen of the uterus (and thus the external environment) via the fallopian tubes in females. In males the peritoneum forms a true blind sac. The vascular supply and nervous innervation of the visceral peritoneum are supplied by the splanchnic vessels and visceral autonomic nerves, respectively. Branches 941
of the intercostal, lumbar, and iliac arteries supply the parietal peritoneum, and the phrenic and intercostal nerves 942
provide nervous innervation. The clinical relevance is that inflammation of the parietal peritoneum is perceived as somatic pain, resulting in a splinted abdominal wall, pain on external palpation, and reluctance to move. Visceral pain is mediated by small type C sensory fibers, which are believed to be stimulated by bowel distention, smooth muscle spasms, tension on the mesentery, and ischemia.

The peritoneal lining functions as a semipermeable barrier to the diffusion of water and low-molecular weight solutes between the blood and the abdominal cavity.[1] The peritoneum secretes a serous fluid that lubricates the abdominal cavity, inhibits adhesion formation, and has minor antibacterial properties.[1,2] Macrophages, mast cells, mesothelial cells, and lymphocytes provide immune function within the peritoneum.[2,3] Peritoneal macrophages impart antibacterial activity via complement receptors, phagocytic activity, interaction with T lymphocytes, neutrophil chemotaxis, and fibroblast activation. The peritoneal surface maintains a high level of fibrinolytic activity through the production of plasminogen activators by mesothelial cells. This function, together with the lubricant properties of the peritoneal fluid, helps to maintain gliding surfaces within the peritoneum and prevent adhesion formation. In quadrupeds, peritoneal fluid produced by the mesothelium tends to move ventrally and cranially, aided largely by diaphragmatic movement. Peritoneal fluid, waste products, and foreign material (including bacteria) exit the peritoneal cavity to enter the lymphatic system through diffusely distributed subendothelial pores or via the large diaphragmatic stomata, depending on particle size. Large molecules and particles greater than approximately 40,000 MW (such as bacteria) exit through the diaphragmatic stomata and ultimately enter the thoracic duct.

Peritonitis is inflammation of the mesothelial lining of the peritoneal cavity and is characterized by desquamation and transformation of mesothelial cells; chemotaxis of neutrophils; release of several soluble mediators of inflammation; exudation of serum, fibrin, and protein into the peritoneal cavity; and depression of fibrinolytic activity.

13.17.2 Etiopathogenisis

Peritonitis occurs in association with a variety of disorders that result in mechanical, chemical, or infectious insult to the peritoneal lining.[1–4] Any process resulting in disruption or irritation of the peritoneal lining, inflammation or infection of abdominal organs, or compromise of the intestinal wall can result in peritonitis (Box 13.17-1). Common mechanical injuries include blunt or perforating trauma to the abdominal wall, breeding and foaling accidents, and abdominal surgery. A variety of traumatic insults of iatrogenic origin can cause 942
peritonitis, such as abdominocentesis, enterocentesis, splenic puncture, bowel trocharization, liver biopsy, 943
uterine biopsy, castration, and rectal tear. Chemical insults of endogenous origin include blood, urine, pancreatic enzymes, bile, gastric juice, chyme, and chyle. Talc, contrast agents, antibiotics, and lavage solutions are additional examples of chemical insults. Traumatic events often involve bacterial contamination at the time of injury and mechanical and chemical injuries can become infected secondarily. The most common manifestation of peritonitis is acute, diffuse, septic peritonitis following inflammation, vascular insult, perforation, or surgical manipulation (enterotomy, resection, anastomosis) of the gastrointestinal tract. The septic process in such cases

involves mixed bacteria of gastrointestinal origin. Penetrating abdominal wounds also result in mixed infections. Less commonly, singular bacterial forms gain access to the peritoneum though hematogenous spread, extension from a contiguous organ, or through the female genital tract. Primary, monomicrobial infections involving *Streptococcus equi, S. zooepidemicus, Actinobacillus equuli,*[6] *Rhodococcus equi,* and *Corynebacterium pseudotuberculosis* are examples. Septicemia, septic omphalophlebitis, ascending urinary tract infections, and uterine infections are additional examples. Parasites also play a role in peritonitis. Verminous arteritis caused by strongylosis can lead to vascular damage (thromboembolism, infarction) to the intestine. The activities of strongyles, ascarids, and tapeworms can result in perforation of the bowel and damage to other abdominal organs. Peritonitis has been associated with viral infections, including influenza, viral arteritis, and African horse sickness virus. Neoplastic diseases also can result in peritoneal inflammation. Although a number of potential causes of peritonitis exist, sepsis is a common and serious complication, and the identification and control of bacterial sepsis is critical for a successful outcome.

Cholelithiasis

Pancreatitis

Retroperitoneal abscess

Neoplasia

Bowel leakage (as well as external trauma) results in contamination of the peritoneum with large numbers of many types of bacteria. The intestinal tract contains a mixed population of bacteria, and the quantity of bacteria and prevalence of anaerobic species increase in the distal segments.[1–7] There are approximately 1×10^9 anaerobic and 1×10^5 aerobic bacteria per milliliter of cecal and colonic fluid, thus the potential for bacterial contamination of the peritoneum is great. High mortality is associated with contamination from the lower bowel because of the large numbers of bacteria present.[8] Hirsch and Jang[9] reported isolation of an infective agent from equine peritoneal fluid in approximately 25% of attempts. Obligate anaerobic bacteria were cultured most frequently, followed by members of the Enterobacteriaceae family *(Escherichia coli)*. Penicillin-resistant *Bacteroides fragilis* was isolated from 10% to 20% of cases. In another study in which bacteria were identified in equine abdominal fluid by cytologic examination or culture, *E. coli* was the organism most commonly isolated.[10] In human beings and laboratory animals the well-established fact is that despite the variety of organisms initially introduced subsequent to these events, established infections are characterized by only a few types of bacteria, which are often gram-negative aerobes and anaerobic bacteria.[2] This selectivity occurs through the processes of selective reduction of bacterial populations and bacterial synergism. A well-known example of synergism in human beings and laboratory animals is peritonitis involving *E. coli* and *B. fragilus*. The presence of each organism is beneficial to the survival of the other, and each is important in the overall pathogenesis of the disease. *E. coli* is associated with septicemia and early mortality, whereas *B. fragilis* infection tends to result in chronic abscessation with delayed morbidity and mortality. Some evidence suggests that in horses, in addition to coliforms and anaerobes, streptococci and perhaps *C. psuedotuberculosis* may survive selective reduction and participate in synergistic infection following polymicrobial contamination.

Biologic events resulting from contamination of the abdomen or injury to the mesothelial cells have been described[1–4] and include release of catecholamines, histamine, and serotonin from peritoneal mast cells; vasodilation and hyperemia; increase in peritoneal vascular permeability; secretion of protein-rich fluid into the peritoneum; transformation of mesothelial cells into macrophages; and influx of polymorphonuclear cells, humoral opsonins, natural antibodies, and serum complement into the peritoneal cavity. Additionally, depression of the peritoneal fibrinolytic activity, fibrin deposits on the peritoneal surface, and sympathetic-mediated ileus of the gastrointestinal tract can occur.

These processes benefit the animal by confining contamination and infection, and indeed, with clean, minimally invasive procedures such as enterocentesis or trocharization, this is effective. However, with greater severity of peritoneal contamination or irritation, these processes are magnified and become deleterious, resulting in problems such as hypovolemia, hypoproteinemia, ileus with resultant bowel distention, ischemia of the bowel

wall with subsequent absorption of bacteria and toxins, and ultimately adhesion and abscess formation. Additionally, systemic responses to bacterial toxins, particularly lipopolysaccharide,[11,12] can compromise the metabolic condition of the patient further. Equine peritoneal macrophages release several mediators when exposed to bacterial lipopolysaccharide,[13] undoubtedly an important component of septic peritonitis.

Pathologic description of peritonitis includes origin (primary or secondary), onset (peracute, acute, chronic), distribution (localized versus diffuse), and presence of bacteria (septic versus nonseptic).[3,4] Clinically, viewing 943

944 the pathogenesis of peritonitis as a series of stages, as reviewed and described by Trent, is useful.[2] The contamination stage, lasting 3 to 6 hours, involves introduction of bacteria into the peritoneum and initiation of the acute inflammatory response previously described. If the organisms are not eliminated and infection is established, the process evolves to the stage of acute diffuse peritonitis. Although the overall movement of contaminants is toward the diaphragmatic stomata and into the thoracic duct, the nature of the peritoneal circulation is such that regardless of the location of the initial contamination, bacteria spread throughout the peritoneum within several hours. The stage of acute diffuse peritonitis lasts up to 5 days. The inflammatory response persists and escalates with continued exudation of proteinaceous fluid and influx of inflammatory cells. Offending organisms are delivered to the lymphatic system and may be eliminated by the immune system. Organisms, however, may gain access to the systemic circulation in sufficient numbers to result in clinically relevant septicemia. In human beings and laboratory animals having undergone polymicrobial contamination of the peritoneum, the organisms causing septicemia at this stage are usually coliforms, *E. coli* in particular. This stage of the disease process has the highest mortality because of the effects of severe peritoneal inflammation, endotoxemia, and septicemia. If the animal survives this stage but fails to eliminate the infection in the peritoneal cavity, the disease enters a transitional phase referred to as the acute adhesive (or localizing) stage. This stage occupies a time frame of perhaps 4 to 10 days after the initial insult. Neutrophils are still active, macrophages are increasing in numbers, and fibrin aggregates are being organized or lysed. In human beings and laboratory animals, selective reduction and synergism continue such that anaerobes and gram-negative aerobes predominate. If infection persists beyond this point, organization of fibrin proceeds and organisms become isolated from host defenses. At this point, the disease process enters the stage of chronic abscessation. This stage can begin as early as 8 days after inoculation and persists indefinitely.

13.17.3 Clinical Signs

Clinical signs of peritonitis depend on the primary disease process, the duration of the problem, and the extent of peritoneal inflammation. Localized peritonitis may have few or no systemic manifestations, whereas severe localized or generalized peritonitis often is accompanied by severe toxemia or septicemia or both. Septic peritonitis usually causes more severe clinical signs because of the inflammatory mediators released in response to bacterial toxins and because of the presence of endotoxin when gram-negative organisms are involved. Most clinical signs are nonspecific and include fever, depression, inappetance, decreased borborygmi, and dehydration. Additional signs, reported in 30 horses (ages 2 months to 16 years) with peritonitis, were colic, ileus, weight loss, and diarrhea.[14]

Horses with peracute peritonitis, as occurs with rupture of the bowel or rectal tear, have severe toxemia, weakness, depression or severe colic, tachycardia, tachypnea, and circulatory failure. Fever may not be present depending on the degree of shock. Typical clinical findings include sweating, pawing, muscle fasciculations, weak peripheral pulses, red to purple mucous membranes, prolonged capillary refill time, and decreased skin elasticity. Parietal pain, characterized by reluctance to move, splinting of the abdominal wall, and sensitivity to external abdominal pressure occur in some acute cases. Urination or defecation may be painful for the horse, and urine and fecal retention may be evident on rectal examination. Palpation of the abdomen externally may elicit

flinching, aversion movements, or groaning. With extensive abdominal fecal contamination, rectal examination may reveal a gritty feeling of the serosal and parietal surface of the peritoneum because of fibrin deposition and a dry texture of the peritoneum. In horses with more chronic peritonitis, rectal examination findings can include pain on palpation of fibrinous or fibrous adhesions, intestinal impaction or distention following ileus and dehydration, an abdominal mass (abscess or neoplasia), or an impression of bowel floating in fluid. In many cases, one can detect no abnormalities on rectal examination.

Horses with localized, subacute, or chronic peritonitis may have signs of chronic or intermittent colic, depression, anorexia, weight loss, intermittent fever, ventral edema, exercise intolerance, decreased or absent intestinal sounds, and mild dehydration. Heart rate and respiratory rate may be normal. Fecal output may be normal; however, horses with chronic diarrhea and weight loss have been reported.[14]

Foals with peritonitis usually exhibit signs of colic (acute or chronic) and are febrile, depressed, and inappetant. In some foals with primary peritonitis, pleural effusion occurs. In young foals, peritonitis can cause rapid metabolic deterioration, and determination and correction of the primary problem requires immediate attention. In older foals, peritonitis may occur insidiously, as occurs following *S. equi* or *R. equi* infections.

13.17.4 Clinicopathologic Findings

13.17.4.1 HEMATOLOGY AND SERUM CHEMISTRY

Clinicopathologic abnormalities vary depending on the time of onset and severity of peritonitis. Horses with 944
acute, septic peritonitis can have leukopenia, hemoconcentration, metabolic acidemia, azotemia, and 945
electrolyte imbalances reflective of systemic inflammation from endotoxemia and hypovolemia. Horses with peritonitis of a few days' duration may have leukocytosis and hyperfibrinogenemia. Plasma protein levels vary depending on the hydration status, degree of exudation into the peritoneum, and type of underlying problem. In chronic peritonitis, hyperproteinemia with hyperglobulinemia may be present.

Neonates with uroperitoneum caused by urinary bladder rupture or urachal disease tend to develop azotemia, hyponatremia, hypochloremia, hyperkalemia, and acidosis. Foals with peritonitis following septicemia, severe enterocolitis, severe meconium impaction, intussusception, small intestinal volvulus, gastric or duodenal rupture, or ascarid impactions usually have clinicopathologic findings reflective of systemic inflammation, such as inflammatory leukogram or leukopenia, hemoconcentration, and acidosis. Chronic abscessation, as occurs in foals with *R. equi* and streptococcal infections, results in clinicopathologic findings reflecting chronic inflammation (anemia, hyperfibrinogenemia, hyperglobulinemia).

13.17.4.2 PERITONEAL FLUID

Abnormalities in the composition of peritoneal fluid occur with peritoneal inflammation, and peritoneal fluid analysis is principal to the diagnosis of peritonitis. One collects peritoneal fluid through puncture of the abdomen on the ventral midline. One should clip and prepare an area aseptically. Usually, the lowest point of the abdomen, 5 to 10 cm caudal to the xiphoid cartilage, is prepared for puncture; although in some cases one may perform paracentesis more caudally, particularly when one suspects a specific area of sequestered fluid or abscessation. In addition, one may choose a site to the right of midline in an attempt to avoid the spleen. One can perform peritoneal puncture using a 1½-inch, 18-gauge needle or, following local anesthesia and a stab incision with a No. 15 scalpel blade, using a sterile cannula. One collects fluid by gravity flow and should collect fluid in a tube containing anticoagulant, preferably EDTA for cytologic examination, and in a sterile

tube without anticoagulant for visual inspection and, if desired, for culture. One should fill the EDTA tube to half its volume, because the EDTA will alter the refractive index of the fluid, resulting in a falsely elevated value for total solids when one collects only a small volume and tests it with a refractometer.

One should evaluate peritoneal fluid routinely as to color, turbidity, total protein, white blood cell (WBC) count and differential, and the presence of bacteria as determined by Gram stain. Normal peritoneal fluid is clear and straw-colored and does not coagulate spontaneously. Peritoneal fluid becomes turbid when increased numbers of white blood cells and concentration of protein are present. Pink or red fluid indicates free hemoglobin or hemorrhage. Blood introduced into the peritoneal fluid iatrogenically in some cases may be differentiated from blood from internal hemorrhage based on the presence of platelets and hematocrit. Fluid with iatrogenic blood contamination contains platelets, whereas fluid with blood following internal hemorrhage or diapedesis often does not have platelets. Blood contamination resulting from splenic puncture often results in the packed cell volume of the sample being greater than that of the blood. Large volumes of dark brown or green fluid with a fetid odor obtained from several sites strongly suggest bowel rupture, but one should perform cytologic examination for confirmation.

The distribution of polymorphonuclear and mononuclear cells varies widely, and one should interpret the results of cell counts and differentials as supporting a number of disorders rather than a specific diagnosis. Normal equine peritoneal fluid contains fewer than 5000 nucleated cells per microliter.[2,15]

WBC counts in acute peritonitis (>100,000/μL) are reported to be higher than those in chronic peritonitis (20,000 to 60,000/μL)[14–16]; however, this is not always the case, and the WBC count depends most on the cause of the peritonitis. The WBC level does not always correlate with severity of peritonitis or the prognosis. The peritoneal fluid WBC count can be greater than 100,000/μL following enterocentesis, with no clinical signs or problem.[17] Conversely, peritoneal WBC counts of fewer than 100,000/μL may be found in foals or horses with intraabdominal abscesses.[18] The peritoneal WBC count can increase to greater than 150,000/μL following celiotomy[19] and can be higher if an enterotomy is done. Postoperatively, the WBC count normally continues to decline and returns to near normal by 5 to 7 days. Failure of the WBC count to decrease suggests peritonitis resulting from a postoperative complication. Finally, peritoneal fluid WBC counts greater than 500,000/μL indicate severe focal or generalized peritoneal sepsis.

The distribution of polymorphonuclear and mononuclear cells varies in normal peritoneal fluid,[2,15] but polymorphonuclear cells usually predominate. With acute peritonitis, polymorphonuclear cells typically increase to a greater degree than mononuclear cells, but this depends on the cause. In horses that have bowel disease accompanied by endotoxemia, the number of peritoneal mononuclear cells increases, as does transformation of mesothelial cells to macrophages. In chronic cases, one easily may mistake transforming mesothelial cells for neoplastic cells, which can make diagnosis difficult, particularly when the presenting problem is compatible with a neoplastic process. In such cases, consultation with a clinical pathologist regarding cytologic findings is prudent. 945

946

Normal peritoneal fluid protein concentration is less than 1.5 g/dl.[15] Protein levels between 1.5 g/dl and 2.5 g/dl can be difficult to interpret, but one should consider levels greater than 2.5 g/dl to be elevated abnormally. Fibrinogen concentration increases with inflammation, and levels greater than 10 mg/dl in the peritoneal fluid suggest that an acute inflammatory process is present.[20] Fibrinogen content will also increase from blood contamination.

The presence of free and phagocytosed bacteria in peritoneal fluid indicates generalized suppuration, abscessation, or compromised bowel. If one observes numerous microorganisms of mixed types free in the peritoneal fluid or if one observes plant material, massive bacterial contamination of the abdomen following bowel rupture likely has occurred. The presence of toxic or degenerate neutrophils and bacteria within polymorphonuclear cells helps to distinguish peritoneal fluid from intestinal contents in such cases. Enterocentesis yields discolored fluid containing mixed microorganisms and plant material and that is largely devoid of white blood cells. Bacterial contamination of a sample can occur during collection of the sample, and iatrogenic contamination of a sample can result in free and intracellular bacteria in peritoneal fluid, particularly if processing is delayed. In such cases the bacterial numbers are few and the neutrophils appear healthy. In some cases of gastrointestinal perforation the luminal material, inflammatory cells, and protein may be sequestered by the omentum and further contained by fibrinous adhesions. Abdominal fluid obtained via standard ventral paracentesis may have low cellularity and protein content but large numbers of mixed bacteria indicating bowel rupture.[5] Examples include gastric rupture along the greater curvature of the stomach between the omental layers (omental bursa) and perforated gastric or duodenal ulcers in foals. Correlating all cytologic findings with clinical and clinicopathologic findings is important for interpreting the results of peritoneal fluid cytologic examination.

Biochemical analysis of peritoneal fluid may be useful in detecting sepsis when cytologic examination and culture are negative or otherwise unavailable. In a prospective study by Van Hoogmoed, Rodger, Spier, et al., peritoneal fluid pH and glucose concentrations from horses with septic peritonitis were significantly lower than horses with nonseptic peritonitis and healthy horses.[21] Peritoneal fluid pH less than 7.3, glucose less than 30 mg/dl, and fibrinogen concentration greater than 200 mg/dl were considered highly predictive of septic peritonitis. Serum to peritoneal glucose concentration differences of greater than 50 mg/dl was considered the most diagnostically useful test for septic peritonitis in the study. Increased activities of alkaline phosphatase, lactic dehydrogenase, creatine kinase, aspartate aminotransferase, tumor necrosis factor, and interleukin-6 have been measured in the peritoneal fluid of horses with abdominal disorders, but the diagnostic and prognostic implications of the presence or absence of these enzymes and analytes is limited.[20–22]

One should submit peritoneal fluid samples in appropriate media (Port-A-Cul Vial, BBL Microbiology System) for aerobic and anaerobic cultures in an attempt to identify the pathogenic organism(s). Obligate anaerobic bacteria such as *Bacteroides* are difficult to culture, because one must collect, transport, and culture the sample under strict anaerobic conditions. Frequently, bacterial cultures are negative when bacteria are present in peritoneal fluid. To enhance recovery of bacteria, one can inoculate peritoneal fluid into blood culture medium (Septi-Chek Columbia, Hoffmann-LaRoche Inc., Nutley, New Jersey), and if the horse has received antimicrobial treatment, one first should pass fluid through an antimicrobial removal device (A.R.D., Becton Dickinson & Co., Cockeysville, Maryland).

13.17.5 Treatment

Early and aggressive therapy is required if treatment of peritonitis is to be successful. The goals of treatment are to resolve the primary problem, minimize the inflammatory response, and prevent long-term complications. In the acute phase, one gives primary consideration to the arrest of endotoxic, septic, or hypovolemic shock; correction of metabolic and electrolyte abnormalities and dehydration; and management of pain. In the absence of blood gas and electrolyte determinations, adequate volumes of a balanced electrolyte solution are required to correct dehydration and support the cardiovascular system. If the plasma protein concentration of the horse is less than 4.0 g/dl, one should consider administration of plasma or synthetic colloids.

One should administer flunixin meglumine (Banamine) for its local and systemic antiinflammatory effects. Dosages vary depending on the severity of peritonitis, degree of toxemia, severity of pain, and hydration status of the horse and range from 0.25 mg/kg intramuscularly or intravenously every 6 to 10 hours to 1.0 mg/kg intramuscularly or intravenously every 12 hours. The higher dosage provides greater visceral analgesia, whereas the lower dosage is effective in modifying the effects of experimental endotoxemia.[23] In addition to analgesic and general antiinflammatory effect, flunixin meglumine may be effective in retarding adhesion formation when administered early in the acute, diffuse stage of septic peritonitis.[2]

Heparin therapy has been recommended to prevent adhesion formation and to render bacteria more susceptible to 946
cellular and noncellular clearing mechanisms. In experimental models using laboratory animals, heparin therapy 947
was associated with decreased adhesions in septic peritonitis.[24] Heparin has not yet been demonstrated clearly to have similar efficacy in horses, although it may. Suggested dosages range from 20 to 40 IU subcutaneously every 12 hours for 48 hours[4] to 40 to 80 IU/kg subcutaneously every 8 hours.[5] One should note that heparin induces red blood cell aggregation in horses,[25] which may adversely affect capillary blood flow.

One should initiate antimicrobial therapy after making a diagnosis of peritonitis and before the results of peritoneal culture are available, because isolating an organism may take several days and often culture fails to isolate the organism(s). Intravenous administration of antimicrobials is preferred over oral or intramuscular routes in acute, diffuse, septic peritonitis because more reliable levels of drug are achieved in the tissues and peritoneal fluid than otherwise would be obtained in horses with hypovolemia or decreased intestinal motility.[26] The combination of a β-lactam antibiotic with an aminoglycoside is appropriate in most circumstances and certainly in the acute diffuse stage of septic peritonitis. These drugs act synergistically to provide a broad spectrum of activity against a variety of gram-positive and gram-negative aerobic and anaerobic bacteria.[27] Potassium penicillin (22,000 to 44,000 IU/kg intravenously every 6 hours) combined with gentamicin (6.6 mg/kg every 24 hours) is an appropriate regimen. In most cases, peritonitis will have resulted from bowel contamination, and thus one should presume a mixed infection with gram-negative aerobic bacteria and gram-positive and gram-negative anaerobic bacteria.[2] One also should presume the same in many cases of traumatic peritonitis, as occurs with foreign body puncture, breeding trauma, or foaling trauma. Therefore a strong possibility exists of infection involving penicillin resistant *Bacteroides fragilis,* so that adding metronidazole (15 mg/kg orally every 6 to 8 hours) to the regimen is prudent. Combination therapy with β-lactam and aminoglycoside antibiotics (and metronidazole when indicated) is a standard and generally effective protocol. One can modify this antimicrobial regimen when culture and antimicrobial sensitivity results become available.

Aminoglycosides and nonsteroidal antiinflammatory drugs have the potential to induce acute renal tubular damage, particularly when dehydration and decreased renal perfusion are present. Therefore adequately rehydrating the patient and ensuring that renal function is intact before initiating treatment with these drugs are important. Furthermore, maintaining hydration and monitoring renal function during the course of treatment are important. Monitoring serum creatinine concentration; performing serial uninalysis observing for pigment, red blood cells; and casts; determining the ratio of γ-glutamyltransferase to creatinine in the urine; and therapeutic drug monitoring[26] of aminoglycoside levels are useful in this regard.

Sodium ampicillin and ceftiofur sodium are β-lactam antibiotics that may be useful in combination therapy. These drugs have an extended gram-negative spectrum compared with penicillin. However, as a third-generation cephalosporin, ceftiofur is less effective against anaerobes than penicillin. One also may consider ceftiofur, trimethoprim-potentiated sulfonamides, amikacin, and enrofloxacin for treatment of gram-negative infection based on culture and sensitivity results. Enrofloxacin is a quinolone drug with excellent activity against gram-

negative pathogens, including *Pseudomonas,*[27] and also can be effective against resistant staphylococci (personal observation). Such staphylococci may be involved in infections caused by traumatic puncture of the abdominal wall. Enrofloxacin has a variety of potential toxic effects, including cartilage damage in young growing animals.[29] However, a recent study concluded the drug was safe when administered to adult horses intravenously at 5 mg/kg every 24 hours for 3 weeks.[30] One probably should avoid using the drug in young, growing animals until the issue of cartilage damage is resolved. Administration of enrofloxacin to horses constitutes off-label usage.

One should treat horses with acute, diffuse, septic peritonitis with antibiotics until the white blood cell count, plasma fibrinogen, and abdominal fluid analysis are normal. In horses that respond to therapy, this process takes a variable amount of time depending on the offending organisms and stage of disease at the time treatment is initiated. Horses with abdominal abscessation resulting from polymicrobial infection may require many months of antibiotic treatment. Abdominal abscesses caused by streptococci and *Corynebacterium pseudotuberculosis* also may require long-term treatment (weeks to months). Long-term antibiotic treatment generally necessitates the use of oral antibiotics, and the options are limited. Trimethoprim-potentiated sulfonamides are administered orally and are effective against a variety of gram-positive and gram-negative organisms, although some streptococci are resistant. Metronidazole is an orally administered drug effective against anaerobic bacteria, as previously discussed. Other orally administered antimicrobials one may consider for long-term use include doxycycline (broad spectrum), erythromycin (gram-positive spectrum), and enrofloxacin (mostly gram-negative spectrum). Importantly, rifampin, when used with other drugs, can be effective in penetrating and resolving abscesses. Combination therapy with erythromycin and rifampin is the standard treatment for *Rhodococcus equi* infection in foals.

Peritonitis caused by *Actinobacillus equuli* usually is manifested as a diffuse, supporative peritoneal exudate.[6] 947
The same is true for some cases involving streptococci (personal observation). These infections generally 948
respond well to combination therapy with penicillin and gentamicin. If streptococci are involved as the sole pathogen, then penicillin alone should be effective. Streptococci potentially can be involved in mixed, synergistic peritoneal infections in horses.[2]

Drainage or lavage of the peritoneal cavity may be of benefit in removing toxic bacterial by-products and products of inflammatory cells.[31] High numbers of inflammatory cells and release of their mediators can persist even after the primary stimulus of the inflammatory response has resolved. Infusing large volumes of isotonic, warmed fluid into the peritoneal cavity also dilutes the inflammatory mediators, possibly reducing their deleterious effects. When successful, peritoneal lavage decreases the peritoneal fluid WBC count and total protein, potentially reflecting a decrease in diffuse inflammation. The benefits of peritoneal lavage are controversial, and a positive effect may be more likely during the acute, diffuse stage of disease.[2,4] Some studies suggest peritoneal lavage, along with heparin therapy, may reduce the incidence of adhesions.[2]

One should perform peritoneal drainage and lavage using a drain of no less than 24F diameter. Foley-type catheters can be used, but “mushroom” drains provide a larger area for fluid to enter the drain. Two approaches to peritoneal lavage are (1) retrograde irrigation through a ventrally placed ingress-egress drain and (2) placement of ingress catheter(s) in the paralumbar fossa(e) for infusion of fluids, with a drain placed ventrally for removal of infused fluid. One must recognize that thorough peritoneal lavage can be achieved only via ventral midline laparotomy.

Complications associated with the use of abdominal drains or repeated peritoneal penetration to drain fluid include retrograde infection, local irritation, pneumoperitoneum, and subcutaneous seepage around the drain and

resultant cellulitis. If the patient is hypovolemic or hypoproteinemic, one should consider volume replacement and administration of plasma before removing large quantities of fluid from the abdomen.

In horses with suspected parasite involvement, such as verminous arteritis, one should give larvicidal doses of an anthelmintic once the condition of the horse is stabilized. Ivermectin, fenbendazole, and thiabendazole have been recommended as larvacidal therapies.

14 CHAPTER 14 DISORDERS OF THE LIVER

Michelle Henry Barton

14.1 The Normal Liver

14.1.1 ANATOMY

The liver is the largest organ in the body, constituting approximately 1% of the body weight in the adult horse.[1] The location of the liver between the gastrointestinal tract and the heart is functionally suited for its metabolic, secretory, excretory, and storage properties. In the normal horse the liver lies mostly to the right of the median, is contained completely within the rib cage, and does not contact the ventral abdominal floor. The most cranial portion of the liver is located in the ventral third of the sixth to seventh intercostal spaces and extends caudad to the right kidney (fifteenth rib). In disease processes resulting in hepatomegaly and in the normal equine neonate the liver may extend beyond the caudal border of the last rib. Right liver lobe atrophy has been described as an uncommon normal anatomic variation in adult horses. However, in 1994, Jakowski[2] hypothesized that right hepatic lobe atrophy in horses is a pathologic condition resulting from long-term compression of the right lobe of the liver by abnormal distention of the right dorsal colon and base of the cecum.

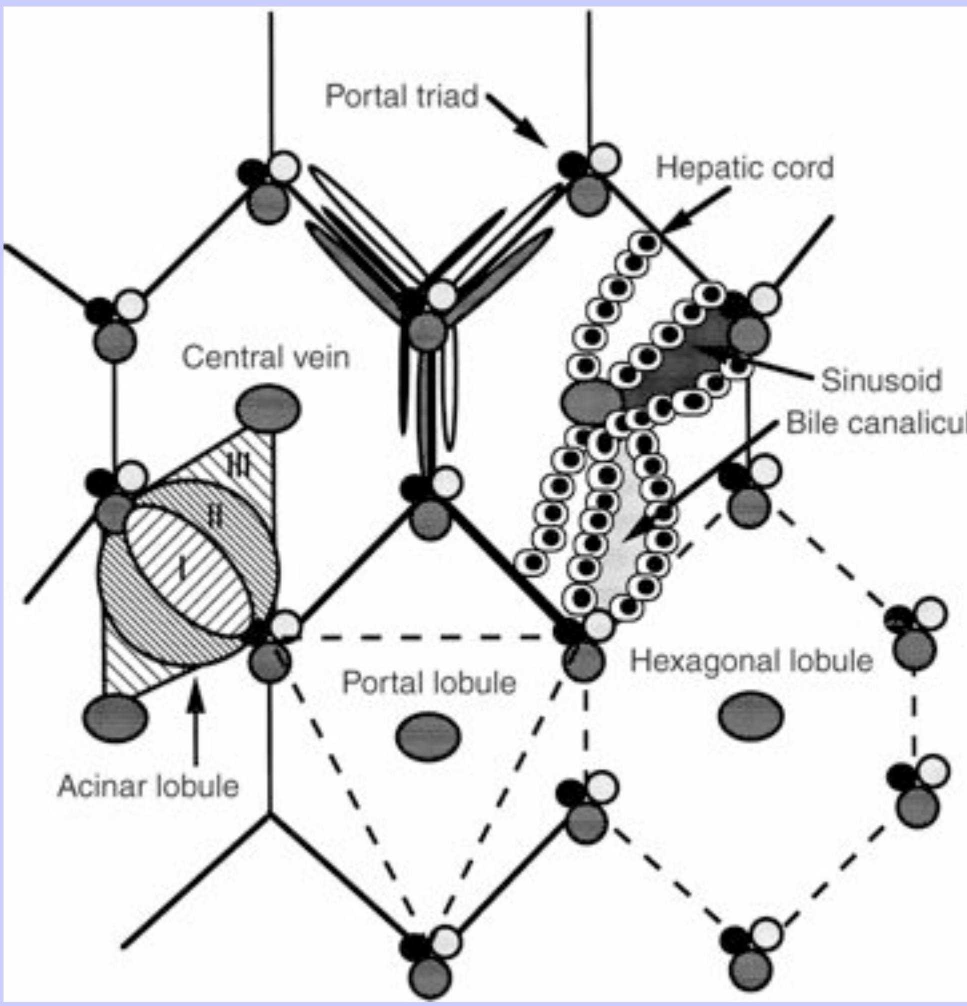
The equine liver consists of two surfaces, diaphragmatic and visceral, and is divided by fissures into four lobes: right, left, quadrate, and caudate. The visceral surface of the liver in situ is malleable and contains impressions of the organs with which it is in contact. The visceral surface also contains the hilum, or *porta* (door), of the liver, through which blood vessels, lymphatics, and nerves enter and the hepatic duct exits. In the horse, six ligaments secure the liver in the abdominal cavity.[1] The *coronary ligament* has two laminae, right and left, that attach the diaphragmatic surface of the liver to the caudal vena cava and the abdominal esophagus. The two laminae of the coronary ligament unite ventrally to form the *falciform ligament*. The falciform ligament, a remnant of the fetal ventral mesentery that extends from the diaphragm to the umbilicus, attaches the quadrate and left lobes to the sternal diaphragm and ventral abdominal floor. The *round ligament*, the remnant of the fetal umbilical vein, is contained within the free border of the falciform ligament. The right and left *triangular ligaments* attach the dorsal right lobe to the right costal diaphragm and the dorsal left lobe to the tendinous center of the diaphragm. The *hepatorenal ligament* connects the caudate process of the quadrate lobe to the right kidney and the base of the cecum.

14.1.2 HISTOLOGIC FINDINGS

At the hilum of the liver a tree of connective tissue consisting of collagen and fibroblasts enters the hepatic parenchyma. The parenchymal cells, or *hepatocytes*, compose approximately 50% to 60% of the mass of the liver and are epithelial cells.[3,4] The hepatocytes are arranged in rows, or *cords*, at least two cells thick that anastomose to form blood passageways called *sinusoids* (Figure 14-1). Hepatic sinusoids are larger than capillaries and are lined with endothelial cells and *Kupffer's cells*. Kupffer's cells are tissue-fixed macrophages and are estimated to make up 20% of the mass of the liver. The endothelial cells make up approximately 20% of the mass of the liver.[4] A cleft, called the *space of Disse*, lies between the hepatocytes and the cells lining the sinusoids. The space of Disse contains fluid similar to the composition of blood but does not contain erythrocytes.

The afferent hepatic blood vessels, bile ducts, lymphatics, and nerves follow the branching connective tissue tree into the hepatic parenchyma. The liver receives approximately one third of the cardiac output. Two separate sources of blood supply the liver and empty into the hepatic sinusoids: the *portal vein* and the *hepatic artery*. The portal vein contains poorly oxygenated blood that carries nutrients absorbed from the gastrointestinal tract to the liver for storage, metabolism, transformation, or packaging for export to other tissues. The hepatic artery contains oxygen-rich blood to support the metabolic and energy-generating activities of the liver. The sinusoids drain into terminal hepatic venules or *central veins*, which connect with the hepatic vein and caudal vena cava. 951 952

Figure 14-1 Histology of the liver. Roman numerals I, II, and III represent zones 1, 2, and 3, respectively, of the acinar lobule.



The space between contiguous hepatocytes in a cord forms a *bile canaliculus* through which bile excreted by the hepatocytes drains into bile ductules and ducts. The bile canaliculi thus are formed solely by the cell membranes of the hepatocytes. The bile ductules and ducts are lined with cuboidal and columnar epithelial cells, respectively, that make up approximately 7% of the mass of the liver.[4] The bile ducts run in the connective tissue tree, adjacent to branches of the portal vein and hepatic artery, toform a distinct *portal tract, radicle, canal*, or

triad (see Figure 14-1). The bile ducts converge at the hilum to form the *hepatic duct*, which drains into the duodenum just distal to the pylorus. Because the horse does not have a gallbladder or a sphincter at the entry site of the hepatic duct into the intestine, the bile is unconcentrated and flows continuously in a direction opposite that of the blood flow in the portal vein and hepatic artery.[1]

The liver can be divided anatomically or functionally into lobules to facilitate histopathologic description of lesions[3] (see Figure 14-1). The *classic hepatic lobule* is delineated by abundant interlobular connective tissue that in cross section roughly appears hexagonal. The corners of the hexagon are defined by three to eight portal tracts with a central vein in the center of the lobule. In contrast, the *portal lobule* is a functional unit describing the exocrine duties of the liver. The three corners of the portal lobule are defined by central veins, with a portal tract situated in the center. The *acinus lobules* describe the vascular supply to the hepatic parenchyma, divided according to the tissue oxygen content. Zone I of the acinus lobule is located immediately adjacent to branching hepatic arteries and portal veins, is the most metabolically active zone, and receives the best oxygen supply. Zone III is located adjacent to central veins, has high mixed-function oxidase activity, is least favorably situated respecting oxygen content, and thus is most susceptible to toxic and hypoxic damage. Zone II is situated between zones I and III.

14.1.3 PHYSIOLOGY

The liver is the main organ involved in regulating nutrient distribution.[5] The majority of nutrients absorbed from the gastrointestinal tract pass directly to the liver via the portal circulation. The incoming nutrients are metabolized for energy, transformed to other nutrient classes, packaged and exported to peripheral tissues, or stored by the liver. The liver is capable of adjusting to the carbohydrate, protein, and lipid load from the gastrointestinal tract and of maintaining consistent blood levels of nutrients between feedings and in response to special needs. In addition to its role in nutrient metabolism and homeostasis the liver is involved in excretion (bile), detoxification, and metabolism of endogenous and exogenous substances and in hematopoiesis.[4]

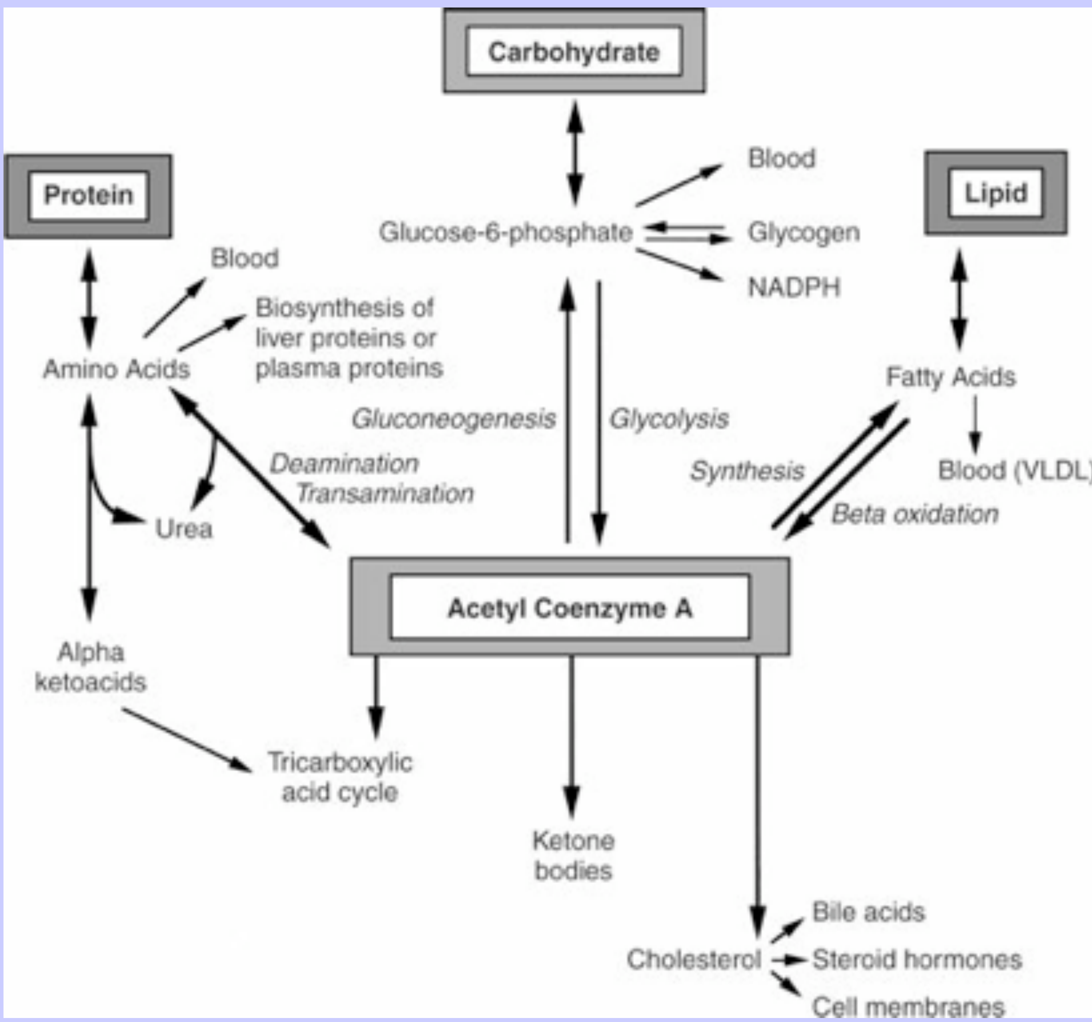
14.1.3.1 Protein Metabolism

Amino acids, which are transported to the liver via the portal or hepatic blood, may be used in the biosynthesis of intrinsic hepatocellular proteins, plasma proteins, porphyrins, polyamines, purines, and pyrimidines.[5] The liver synthesizes 90% of the plasma proteins, including albumin, factors involved in coagulation and fibrinolysis (fibrinogen and factors II, V, VII to XIII, antithrombin III, protein C, plasminogen, plasminogen activator inhibitor, α_2-antiplasmin, α_2-macroglobulin, and α_1-antitrypsin), transport proteins (haptoglobin, transferrin, ceruloplasmin, hormone transport proteins), and acute phase reactant proteins (α- and β-globulins).[4] The liver is the only site of synthesis of albumin and fibrinogen.

The liver is also capable of transamination, or the reversible transfer of an amino group on one amino acid to 952
an α-keto acid, thus forming a new amino acid and a new keto acid. If the liver receives an excess of amino 953
acids or if carbohydrates are unavailable as an energy source, the liver deaminates the amino acids and converts them to pyruvate, acetoacetate, and intermediates of the tricarboxylic acid cycle[5] (Figure 14-2). These intermediates may be oxidized for energy or used as precursors in *gluconeogenesis*, the synthesis of glucose from noncarbohydrate precursors. Endogenous and exogenous glucocorticoids, glucagon, and thyroid hormone act directly on the liver to increase gluconeogenesis(Figure 14-3). Simultaneously, glucocorticords indirectly influence liver gluconeogenesis by promoting peripheral protein catabolism, thus increasing the availability of amino acids. Insulin inhibits gluconeogenesis in the liver.[6]

In addition to protein synthesis and gluconeogenesis the liver plays an important role in eliminating the major toxic by-product of amino acid catabolism, *ammonia*.[7,8] All tissues and intestinal microflora generate ammonia, which subsequently is released into the circulation. One method by which the liver, as well as certain peripheral tissues, eliminates ammonia is by synthesizing nonessential amino acids from α-keto acids and ammonia in a reversal of deamination. A fundamental reaction in the synthesis of nonessential amino acids is the formation of *glutamate* from α-ketoglutarate and ammonia (Figure 14-4). Subsequently, glutamate is used in transamination reactions to form other amino acids. Glutamate also participatesin the conversion of cytotoxic free ammonia into a nontoxic transport form, *glutamine*. Glutamine may be delivered to the kidney, converted back to free ammonia and excreted, or delivered to the liver for urea synthesis.

Figure 14-2 Role of the liver in the metabolism of nutrients. *VLDL*, Very-low-density lipoprotein; *NADPH*, nicotinamide adenine dinucleotide phosphate.



The liver has sole responsibility for converting free ammonia or glutamine into *urea*, the principal form of amino group nitrogen excretion by mammals.[4] Urea is formed by the irreversible condensation of two ammonia molecules with carbon dioxide (see Figure 14-4). The reaction takes place in the hepatocyte mitochondria viathe Krebs-Henseleit cycle.[5] The newly formed urea is released from the hepatocyte, secreted into the sinusoidal blood, and transported to the kidney as *blood urea nitrogen (BUN)* for excretion.

14.1.3.2 Carbohydrate Metabolism

The liver is responsible for the synthesis, storage, and release of glucose.[5] Monosaccharides absorbed from the
gastrointestinal tract are delivered via portal blood tothe liver. In the hepatocyte the majority of glucose is 953
phosphorylated to *glucose-6-phosphate* by the enzyme hexokinase (see Figure 14-2). The remaining glucose is 954
released into the systemic circulation. Other monosaccharides (fructose, galactose) are phosphorylated and converted in the liver to glucose-6-phosphate. The majority of glucose-6-phosphate is converted to glycogen for storage. A small amount of glucose-6-phosphate is oxidized to form adenosine triphosphate, though the major source of adenosine triphosphate in the liver is amino acid and fatty acid oxidation. Approximatelyhalf of the liver glucose enters the phosphogluconate pathway for generation of nicotinamide adenine dinucleotide phosphate, which is required as a reducingagent in the biosynthesis of fatty acids and cholesterol.
Glucocorticoids, catecholamines, glucagon, and thyroid hormone increase gluconeogenesis and 954
glycogenolysisin the liver, whereas insulin inhibits gluconeogenesis[6] (see Figure 14-3). 955

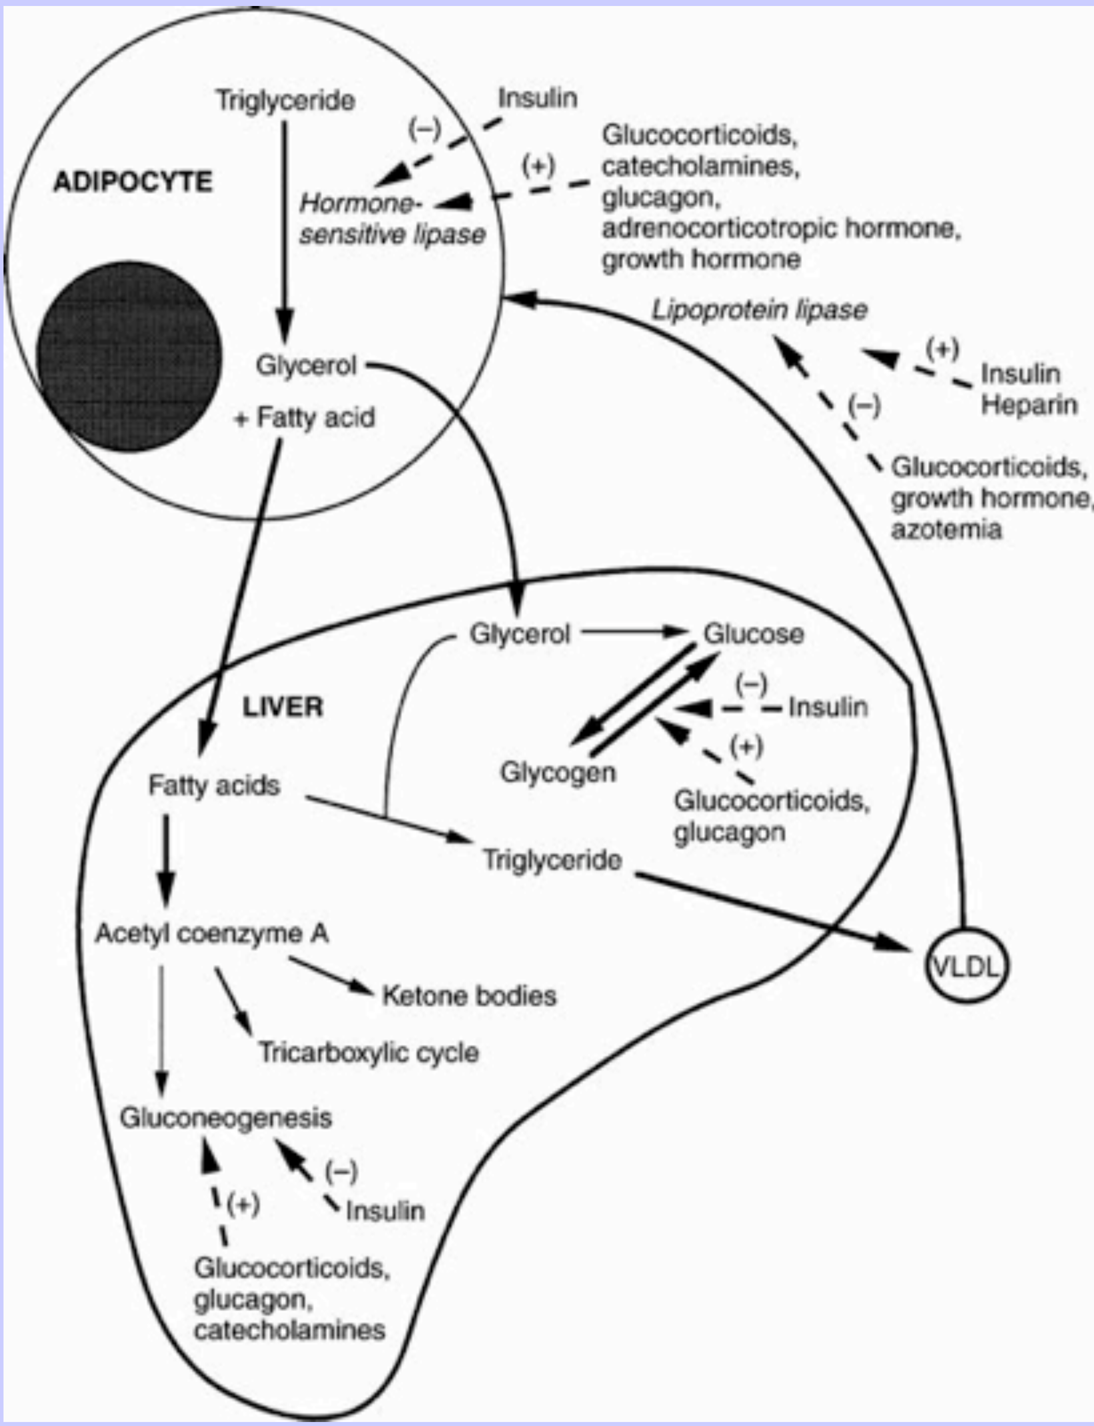

Figure 14-4 The urea cycle.

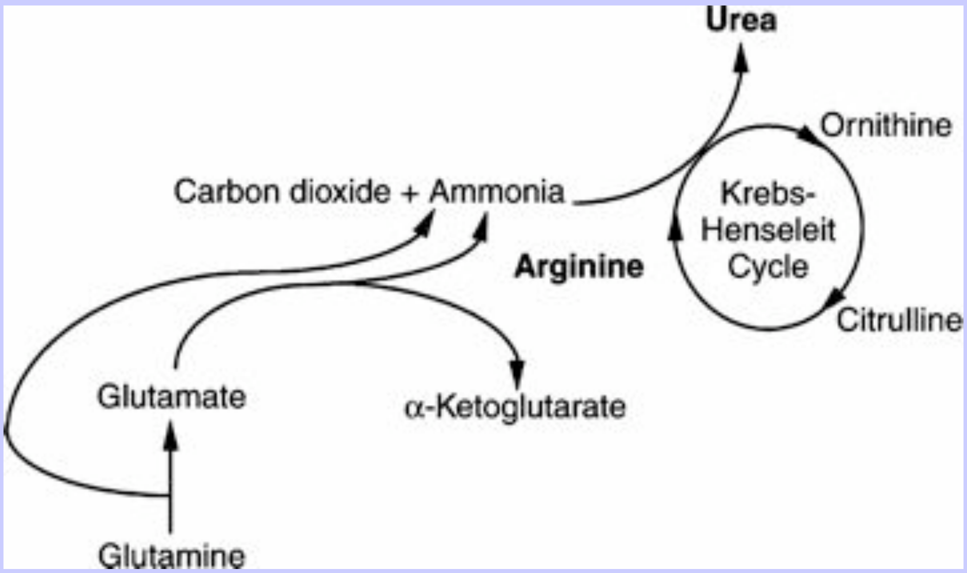


14.1.3.3

Lipid Metabolism

Short-chain fatty acids (fewer than 10 carbon atoms) can be absorbed directly from the gastrointestinal tract, bound to albumin, and delivered to the liver via the portal circulation.[5] However, most short-chain fatty acids are incorporated into phospholipid or triglyceride by the intestinal epithelium and transported to the liver viathe portal blood. The remaining fatty acids absorbed from the gastrointestinal tract are transported as triglyceride in *chylomicrons*. After formation in the intestinal epithelial cells and absorption into lymphatics, chylomicrons enter the systemic circulation via the thoracic duct and subsequently are delivered to the liver. The liver also may take up albumin-bound fatty acids released from adipose tissue.

The fate of fatty acids in the liver depends on the state of energy demand, the rate of fatty acid delivery, and hormonal influences. The primary role of the liver in lipid metabolism is to esterify free fatty acids into triglycerides for export to other tissues[5] (see Figure 14-3). The triglycerides are packaged with protein, carbohydrates, and cholesterol in the endoplasmic reticulum of the hepatocyte into *very-low-density lipoproteins (VLDLs)*, which primarily contain triglyceride, and *high-density lipoproteins*, which primarily contain protein and phospholipid.[9] The VLDLs and high-density lipoproteins are released into the hepatic sinusoids. Once VLDLs are in the systemic circulation, adipose tissue takes them up or endothelial cell lipases alter their composition by removing triglyceride, forming *intermediate*- and *low-density lipoproteins*.

In addition to exporting plasma lipoprotein, the liver can oxidize free fatty acids for energy to acetyl coenzyme A, a fundamental compound in the tricarboxylic acid cycle (see Figure 14-2). The acetyl coenzyme A thus formed also may be used to synthesize other fatty acids, cholesterol, steroids, and ketone bodies, acetoacetate, and β-hydroxybutyrate.[10] Furthermore, through the synthesis of acetyl coenzyme A from glucose and most amino acids, the liver is capable of converting carbohydrates and proteins into lipids. Ketone bodies can be exported from the liver and used for energy by peripheral tissues, especially the brain, when glucose is deficient. However, overproduction of ketone bodies can be detrimental, resulting in ketoacidosis.[9]

Insulin and glucocorticoids closely regulate lipid metabolism[6] (see Figure 14-3). Glucocorticoids function primarily to increase fatty acid mobilization from the periphery, whereas insulin decreases adipose tissue release of fatty acids by activating lipoprotein lipase and inhibiting hormone-sensitive lipase. Insulin acts on the liver to increase fatty acid synthesis from glucose.

14.1.3.4 Excretion of Bile

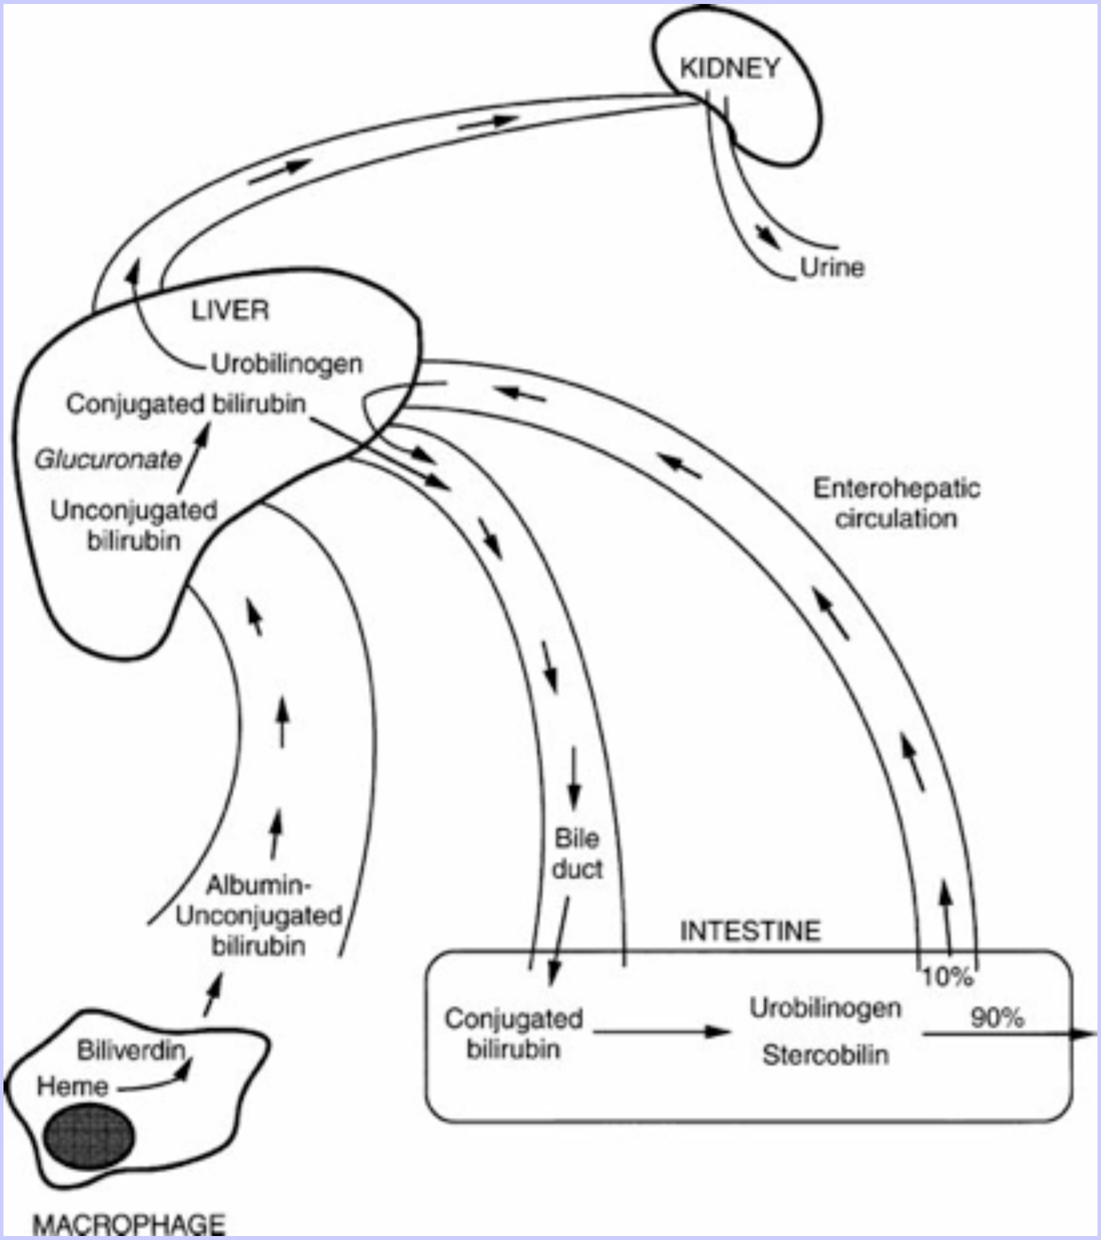
Bile consists of several components, including conjugated bilirubin, bile acids, cholesterol, lecithin, water, and electrolytes.[4] Bile is released by hepatocytes into the bile canaliculi where water diffuses passively. Bile then is transported by large bile ducts and the hepatic duct to the intestine. Water and electrolytes exchange takes place between the bile and the bile duct epithelium; however, isotonicity is maintained. Because the horse does not have a gallbladder or a sphincter at the site of entryof the hepatic duct into the duodenum, the bile is unconcentrated and flow is continuous.[1]

Bile acids make up 90% of the organic portion of bile. Bile acids are amphoteric molecules that act as detergents. These detergents facilitate the excretion of cholesterol and phospholipid from the liver into bile and facilitate the absorption of lipids and lipid-soluble compounds (vitamins A, D, E, and K) from the intestinal tract. The principal *primary bile acids* (i.e., nondegraded) in the horse are *cholate* and *chenodeoxycholate*, which are conjugated with taurine. Once secreted into the lumen of the intestinal tract, cholate and chenodeoxycholate may be reabsorbed or degraded by bacteria, forming the *secondary bile acids deoxycholate* or *lithocholate*, respectively. More than 95% of the conjugated bile acids excreted in bile and released into the intestinal lumen are reabsorbed bythe ileum and returned to the liver via the *enterohepatic circulation*. Deoxycholate acts as a normal bile acid and can undergo enterohepatic circulation, whereas lithocholate is reabsorbed only once. Bile acids are estimated to be recycled at least 38 times a day in healthy ponies.[11]

Bilirubin is the breakdown product of tetrapyrroles that function as electron transport pigments.[4] Most bilirubin is formed from hemoglobin and myoglobin, but nonheme pigments such as the cytochromes also serve as a source of bilirubin. Macrophages in the spleen, bone marrow, and liver (Kupffer's cells) engulf the pigments, convert them to biliverdin (Figure 14-5), convert biliverdin to bilirubin, and then release it from the cellas free, insoluble bilirubin. This form of bilirubin also is referred to as *indirect reacting* or *unconjugated bilirubin*. Unconjugated bilirubin is bound with albumin in the plasma to decrease its hydrophobicity and is delivered to the liver. At the surface of the hepatocyte, the bilirubin is transferred from albumin to *ligandin*, an intrahepatic transport and storage protein.[4,11] Within the hepatocyte the bilirubin is conjugated with glucuronide in the endoplasmic reticulum. *Conjugated bilirubin*, also called *direct reacting bilirubin*, is water soluble and is excreted into the bile canaliculi. Under normal circumstances, little conjugated bilirubin escapes into the general circulation.

Microflora in the intestinal tract reduce conjugated bilirubin to *urobilinogen* and *stercobilin* (see Figure 14-5), 955
which impart a yellow-brown color to feces. In herbivores the presence of chlorophyll pigments in the 956
fecesmasks the color of urobilinogen.[12] Only in the neonatal herbivore receiving a milk diet are the feces yellow. Urobilinogen is absorbed by the intestinal mucosa and transported back to the liver via the enterohepatic circulation. A small amount of conjugated bilirubin in the intestinal lumen is hydrolyzed to unconjugated bilirubin and subsequently is reabsorbed. The liver extracts most of the urobilinogen; however, a small amount spills over into the urine. Urobilinogen is concentrated in the normally alkaline urine of horses and thus is detectable.[13]

Figure 14-5 Metabolism and excretion of bile.



14.1.3.5

Detoxification

The liver is responsible for the *biotransformation* of numerous endogenous and exogenous compounds. Biotransformation involves a series of enzymatic reactions that alter the physical properties or activity of compounds. Biotransformation occurs in two phases.[14] In phase 1, polar groups are added to the compound or existing polar groups are exposed by oxidation, hydroxylation, deamination, or reduction. In phase 2 the product of phase 1 is conjugated, usually with glucuronate or sulfate. Substrates for detoxification usually are

water insoluble, and biotransformation renders them more susceptibleto renal or biliary excretion.[4,15] Examples of endogenous substances biotransformed by the liver include ammonia, bilirubin, and steroid hormones (estrogen, cortisol, aldosterone). The liver biotransforms countless exogenous substances; for example, drugs, plant toxins, insecticides, and mercaptans.

Phase 1 of biotransformation occurs primarily on the enzyme-bound systems of the endoplasmic reticulum, called *microsomes*.[4,15] Most of these enzymes are iron-containing enzymes of the P-450 system, thus named because they absorb light at 450 nm. The P-450 enzymes also are called *mixed function oxidases*. Some substrates, referred to as *inducers*, are capable of saturating the enzymes involved in biotransformation. Enzyme saturation and induction causes hypertrophy of the endoplasmic reticulum and all contained enzymes, 956
thus accelerating substance removal rates. Inducers not only accelerate their own removal rate but also may 957
accelerate the biotransformation of other endogenous and exogenous substances. Examples of enzyme inducers are the barbiturates, phenylbutazone, and chlorinated hydrocarbons. Other agents presented for biotransformation may inhibit microsomal enzymes—for example, chloramphenicol, cimetidine, organophosphates, morphine, and quinidine—thus prolonging the effect of other substrates. Hepatic biotransformation sometimes results in the formation ofa toxic metabolite from a nontoxic parent compound, examples being aspirin and halothane.[15]

14.1.3.6 Mononuclear Phagocyte System

Hepatic macrophages, or Kupffer's cells, make up a major portion of the mononuclear phagocyte system. Cellsof the mononuclear phagocyte system are derived from bone marrow myeloid progenitors and serve two main functions: phagocytosis and to act as antigen-processing cells for lymphocytes. Kupffer's cells respond to opsonins and synthesize a vast array of inflammatory mediators, including interleukins, tumor necrosis factor, and eicosanoids. Unlike other macrophages in the mononuclear phagocyte system, Kupffer's cells function mainly in phagocytosis and are located strategically along the hepatic sinusoids, where portal blood can be cleansed, for example, of bacterial endotoxin, before exposure to the hepatocytes and subsequently the systemic circulation.[16] Kupffer's cells also help cleanse systemic blood entering via the hepatic artery by removing fibrin degradation products, tissue plasminogen activators, hemoglobin, microbes, foreign antigens, and other particulate debris.

14.1.3.7 Miscellaneous Functions

The liver serves as a storage site for several vitamins and trace minerals, including vitamins A, D, and B_{12}, copper, and iron. Vitamin D is converted first in the liver to25-hydroxycholecalciferol and exported to the kidney, where it is transformed into 1,25-dihydroxycholecalciferol, the active form of the vitamin.[6] In the fetus the liver is involved in *hematopoiesis*.[4] In the adult the bone marrow serves as the primary site for hematopoiesis; however, the liver may serve as an extramedullary site of hematopoeisis under intense conditions of erythrocyte regeneration or if a large portion of the bone marrow is destroyed.

14.2 Hepatic Insufficiency

14.2.1 DEFINITION

Hepatic insufficiency or failure refers to the inability of the liver to perform its normal functions properly. Because the liver is involved in such a diverse array of physiologic activities, any pathologic process may hinder one or several functions without impeding others. Furthermore, most hepatic functions are not impaired until greater than 80% of the hepatic mass is lost.[4,12,17] The liver also has the capability to regenerate under certain conditions. If hepatocyte loss is gradual and regeneration parallels destruction, hepatic failure does not necessarily ensue. Thus hepatic disease may be present without accompanying hepatic failure. Consequently, hepatic disease does not always manifest clinically.

14.2.2 PATTERNS AND PATHOLOGIC FINDINGSOF HEPATIC INJURY

The severity of the accompanying clinical signs andthe course of hepatic disease vary depending on the pattern, location, rate, and extent of hepatic damage. Hepatic injury may be reversible (fatty degeneration, cloudy swelling), irreversible (necrosis), focal or zonal, generalized, acute, chronic, inflammatory, anatomic, or functional.

14.2.2.1 Acute Focal or Multifocal Hepatic Injury

Focal hepatic injury occurs with uniform damage to one small area of the liver. Examples of focal hepatic injury include hepatic abscesses, solitary infarctions, and neoplastic growths. Because adequate hepatic reserve exists in the unaffected regions, focal hepatic injury rarely is accompanied by clinical signs of hepatic failure, though evidence of hepatic disease may be demonstrable.[14] Acute multifocal hepatic injury is more likely to result in clinically significant hepatic disease. Acute hepatic injury may be degenerative, necrotizing, or inflammatory. Hepatic *degeneration* refers to a toxic or immunologic insult that causes hepatocytes to swell and take on an edematous appearance. *Ballooning degeneration* is used to describe irregularly clumped cytoplasm with large clear areas. If biliary material has been retained, the hepatocytes appear foamy and swollen *(foamy degeneration)*. *Ischemic coagulative necrosis* refers to poorly stained and mummified hepatocytes with lysed nuclei, whereas *lytic necrosis* describes osmotically swollen and ruptured cells. Necrosis of contiguous hepatocytes that spans adjacent lobules in a portal to portal, portal to central, or central to central fashion is called *bridging necrosis*.[18]

Hepatic injury may be zonal, that is, affecting certain zones of the liver uniformly throughout the entire organ.[14] The liver often appears pale with an enhanced lobular pattern on the cut surface. The two most common types of zonal hepatic injury are centrilobular and periacinal. In *centrilobular zonal injury*, the area adjacent to the central veins (zone III) is affected uniformly, whereas in *periacinal* or *(paracentral) zonal injury*, cellular degeneration involves only a wedge around the central vein (see Figure 14-1). Hepatocytes in these locations 957
are most susceptible to anoxic damage, because the normal oxygen tension is lowest and mixed function 958
oxidase activity is the greatest in these areas. Examples of disease states resulting in centrilobular injury are severe acute anemia, passive congestion caused by congestive heart failure *(nutmeg liver)*, and toxic hepatopathies. Periportal (zone I acinar lobular) injury is rare but may occur with infarction of hepatic vessels, as may occur during verminous arteritis, or exposure to toxins that do not require metabolism by mixed function oxidases (e.g., phosphorus).

14.2.2.2

Acute Generalized Hepatic Injury

Acute generalized hepatic injury often is accompanied by clinical signs of hepatic failure, with the extent of damage dictating the severity of the clinical signs.[14] Typically, the liver appears pale and enlarged and is often friable. Acute generalized hepatic injury may result from infection, necrosis, inflammation, or hepatotoxic agents.[4] Bacterial or viral infections, parasitic infestations, or immune disorders may cause acute generalized necrosis or inflammation. Despite its cause, any process that results inan inflammatory response in the hepatic parenchyma is referred to as *hepatitis*. Acute inflammation most commonly accompanies necrosis and is characterized by the presence of neutrophils and lymphocytes in the areas of cell death or surrounding portal triads. An inflammatory process primarily involving the biliary system is called *cholangitis*, usually resulting from ascending infection from the intestinal tract or following cholestasis.

14.2.2.3

Chronic Generalized Hepatic Injury

Chronic hepatic injury is accompanied by clinical signs of hepatic failure when greater than 80% of the hepatic mass is destroyed or replaced by fibrosis.[4,17] Fibrosis, the presence of collagen and fibroblasts, occurs when the rate of ongoing necrosis exceeds the rate of regeneration. Typically, the liver appears smaller than normal. Fibrosis commonly follows conditions resulting in chronic hypoxia, chronic inflammation, chronic cholangitis or cholestasis, metastatic neoplasia, trauma, or ingestion of antimitotic agents such as plants containing pyrrolizidine alkaloids. *Cirrhosis*, or an *end-stage liver disease*, refers to chronic hepatic disease characterized by the presence of widespread fibrosis, nodular regeneration, and biliary hyperplasia.[14] *Nodular regeneration*, or islands of hepatocytes, occurs when the normal architecture and blood supply of the liver are disrupted or destroyed by the presence of fibrosis. *Bridging fibrosis* implies fibrosis that extends from one portal area to another or from portal areas to central areas.[18] The cause of biliary hyperplasia during chronic liver disease is unknown. One form of chronic hepatic disease, called *chronic active hepatitis*, is characterized by the presence of cirrhosis and an acute inflammatory response.[14]

14.2.2.4

Anatomic or Functional Injury

Anatomic or functional shunts cause liver injury by anoxic damage. Additionally, if blood habitually bypasses the liver, the liver cannot perform its normal metabolic regulatory or detoxifying functions, thus clinicalsigns of hepatic failure become imminent. Anatomic shunts can be congenital or acquired, intrahepatic or extrahepatic.

14.2.3

CLINICAL SIGNS OF HEPATIC INSUFFICIENCY

The clinical signs of hepatic insufficiency vary greatly, are nonspecific, and depend on the extent and duration of hepatic disease (Box 14-1). Usually, greater than80% of the liver mass must be lost before clinical signs become apparent, regardless of the cause of hepatic disease. Thus despite the duration of hepatic disease, the onset of clinical signs is often abrupt. The most common clinical signs of hepatic insufficiency in horses are depression, anorexia, colic, hepatic encephalopathy, weightloss, and icterus.[19–22] Less commonly reported clinicalsigns 958
include hepatogenic photosensitization, diarrhea, abdominal pain, bilateral laryngeal paralysis, and hemorrhagic 959
diathesis. Rarely reported clinical signs of hepatic insufficiency in horses are ascites, dependent abdominal edema, steatorrhea, tenesmus, generalized seborrhea, pruritus, endotoxic shock, polydipsia, and hemolysis. The

appearance of specific clinical signs of hepatic disease often reflects the type of hepatic function(s) that is altered.

14.2.3.1 BOX 14-1 CLINICAL SIGNS OF LIVER DISEASE

14.2.3.1.1 Common Signs

Depression

Anorexia

Colic

Hepatic encephalopathy

Weight loss

Icterus

14.2.3.1.2 Less Common Signs

Photosensitization

Diarrhea

Bilateral laryngeal paralysis

Bleeding

Ascites

Dependent edema

14.2.3.1.3 Rare Signs

Steatorrhea

Tenesmus

Generalized seborrhea

Pruritus

Endotoxic shock

Polydipsia

Pigmenturia (yellow-brown with bilirubinuria; red-brown with hemoglobinuria)

14.2.3.2

Hepatic Encephalopathy

Hepatic encephalopathy (HE) is a complex clinical syndrome characterized by abnormal mental status that accompanies severe hepatic insufficiency.[23–25] Clinical signs vary greatly but represent manifestations of augmented neuronal inhibition. This syndrome occurs in patients with advanced decompensated liver disease of all types and may be a feature of acute, subacute, or chronic hepatocellular disease. HE generally is considered a potentially reversible metabolic encephalopathy.[24] Whether multiple episodes of HE could lead to irreversible neuronal damage is uncertain.

14.2.3.2.1

Clinical Signs and Laboratory Findings

No specific features of HE allow one to distinguish this syndrome from other causes of cerebral dysfunction. The earliest phase of HE probably is missed in most equine patients because it represents minimal behavioral changes with subtle impairment of intellect caused by bilateral forebrain dysfunction[26] (stage I; Table 14-1). In human beings these early signs are more apparent to close friends and family members than to a physician. As encephalopathy progresses, motor function, intellectual abilities, and consciousness become impaired, and generally at this stage (corresponding to stage II) horses become obviously affected. Clinical signs include depression, head pressing, circling, mild ataxia, aimless walking, persistent yawning, and other manifestations of inappropriate behavior. Somnolence develops next: the horse is rousable but responds minimally or excessively to the usual stimuli. At this stage (III) the horse often manifests aggressiveor violent behavior interspersed with periods of stupor. Finally, consciousness fades, the horse becomes recumbent, and coma ensues. Occasionally, seizures occur during the later stages of HE, but in general they are atypical. The severity of encephalopathy corresponds to the degree of hepatic dysfunction; however, neither of these parameters correlates with type or reversibility of the underlying hepatic disease.

TABLE 14-1 Clinical Stages of Hepatic Encephalopathy

STAGE	MENTAL STATUS
I	Mild confusion, decreased attention, slowed ability to perform mental tasks, irritability
II	Drowsiness, lethargy, obvious personality changes, inappropriate behavior, disorientation
III	Somnolent but rousable, marked confusion, amnesia, occasional aggressive uncontrolled behavior
IV	Coma

14.2.3.2.2

Cause and Pathophysiology

By definition, the cause of HE is insufficient hepatocellular function, irrespectiveof the cause of the liver disease. Whether a normally functioning liver is necessary to maintain normal brain neuron and astrocyte function is unclear. The pathogenesis of HE remains unclear, and considering the numerous proposed

hypotheses, the cause almost certainly is multifactorial. The following mechanisms have been suggested for the development of HE, and any or all factors may be involved to greater or lesser degree:

1. Gastrointestinal-derived neurotoxins
2. False neurotransmitter accumulation following plasma amino acid imbalance
3. Augmented activity of γ-aminobutyric acid (GABA) in the brain
4. Increased permeability of the blood-brain barrier
5. Impaired central nervous system (CNS) energy metabolism

Perhaps the oldest and most predominant hypothesis for HE involves the accumulation of toxic materials in the blood, derived from the metabolism of nitrogenous substrates in the gastrointestinal tract, that bypass the liver through functional or anatomic shunts.[23,27,28] Accordingly, HE may be caused primarily by failure of the liver to remove certain substances adequately from the blood that have the direct or indirect ability to modulate function of the CNS. Ammonia, following the degradation of amino acids, amines, and purines by enteric bacteria, has been supported widely as a major neurotoxin of hepatic disease.[28–30] In patients with liver failure, ammonia is metabolized insufficiently, thus plasma concentrations increase and ammonia enters the CNS, where it may cause encephalopathy.[28,31] Ammonia has a toxic effect on cell membrane neurons by inhibition of Na^+,K^+-ATPase (adenosine triphosphatase) activity in nerve cell membranes, causing depletion of adenosine triphosphate.[30,32] Hyperammonemia also is associated with a disturbance in CNS energy production caused by alterations inthe tricarboxylic acid cycle that result in a decrease inα-ketoglutarate formation and increased synthesis of glutamine.[33] Astrocytes in the brain also detoxify ammonia by converting it to glutamate and glutamine. Glutamine accumulation in astrocytes is a major cause of cell swelling and generation of cerebral edema in acute fulminate hepatic failure. Another effect of prolonged exposure of neuronal tissue to ammonia is downregulation of glutamate receptors. Because 959
glutamate is the major excitatory neurotransmitter on the mammalian brain, decreased glutamate receptor 960
activity likely contributes to the decreased excitatory transmission in HE.[32] Hyperammonemia also induces generation of nitric oxide, which leads to accumulation of peroxides, oxidative stress, and nerve cell damage. These cumulative effects of ammonia on neural tissue certainly play an important role in the pathogenesis of HE. Experimentally, ammonia can induce encephalopathy,[34] and children with hyperammonemia caused by congenital enzyme deficiencies have encephalopathy.[29] Furthermore, therapy aimed at reducing the absorption of ammonia from the intestine tends to ameliorate HE.[26] Points argued against the role of ammonia in the pathogenesis of HE are that plasma ammonia concentrations correlate poorly with the severity of HE and ammonia does not induce the electroencephalogram changes typical of the encephalopathy of liver disease.[24,35] Thus the actions of ammonia on the CNS are complex, and ammonia likely is involved in but is not solely responsible for HE.

The synergistic neurotoxins hypothesis for the pathogenesis of HE implicates not only ammonia but also other gut-derived neurotoxins, specifically mercaptans, short-chain fatty acids, and phenols. Members of each of these classes of substances increase in the blood of patients with hepatic failure in concentrations that alone are insufficient to induce encephalopathy. However, the combination of some or all of them may induce encephalopathy by their synergistic actions and by augmenting endogenous metabolic abnormalities,[26,27] mostly centering around inhibition of brain Na^+,K^+-ATPase with subsequent impaired

neurotransmission.[24] As with ammonia, blood and brain concentrations of mercaptans correlate poorly with the stage of HE.[36]

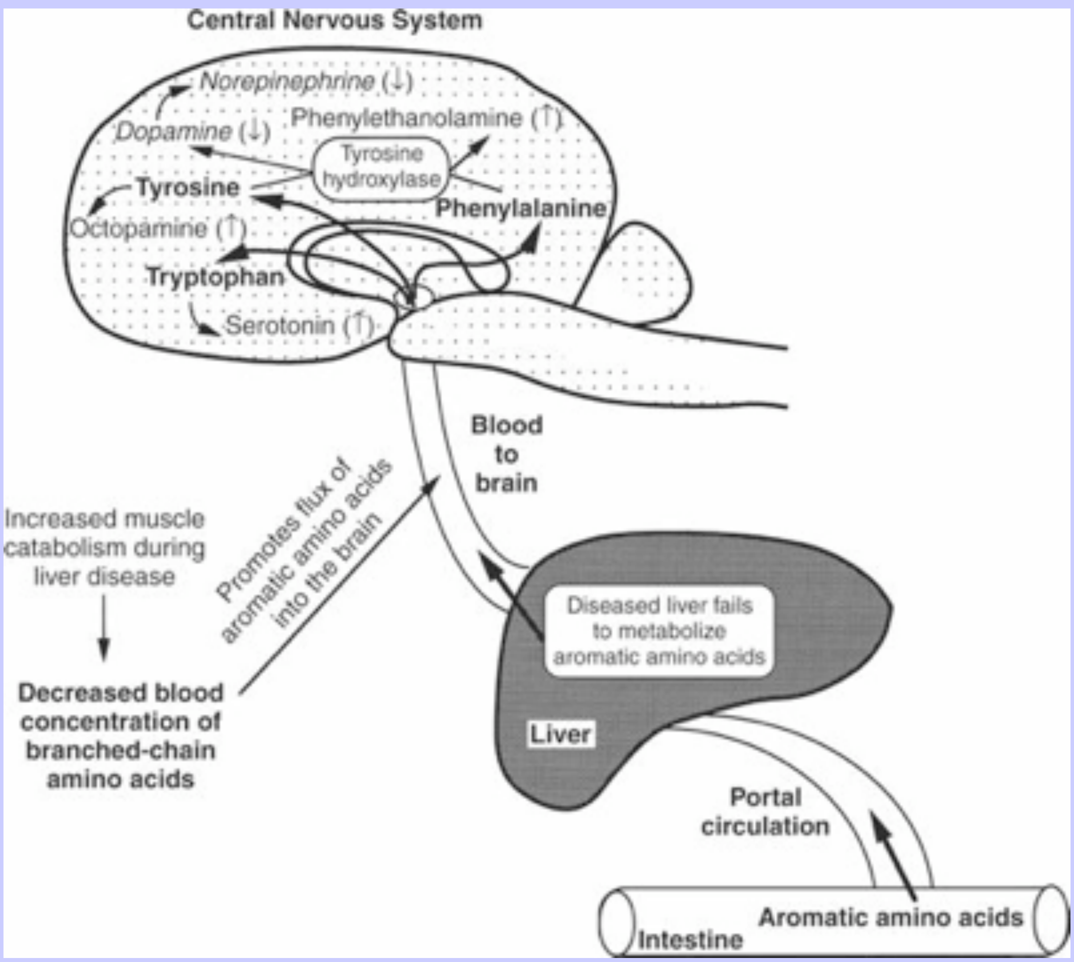
A separate hypothesis holds that during liver failure, true neurotransmitters in the CNS such as norepinephrine and dopamine become depleted and false neurotransmitters, especially octopamine and phenylethanolamine, increase.[25,37] The net neurophysiologic effect of such changes is reduced neuronal excitation and increased neural inhibition. The mechanism of this effect is related to the increased serum concentrations of aromatic amino acids (AAAs: phenylalanine, tyrosine, tryptophan) and decreased concentrations of branched-chain amino acids (BCAAs: valine, leucine, isoleucine) that occur in liver failure.[38,39] Serum glucagon increases in hepatic failure, leading to muscle catabolism and release of amino acids. However, hepatic metabolism of AAAs is reduced, and because BCAAs are metabolized by muscle and adipose tissue, a relative increase in AAAs and decrease in BCAAs occurs. The decreased plasma BCAA:AAA ratio during liver failure and increased brain glutamine concentration (presumably a consequence of ammonia retention) are considered to promote an influx of AAAs into the brain and efflux of glutamine from the brain by exchange transport processes at the blood-brain barrier.[24] Phenylalanine can compete with tyrosine for tyrosine hydroxylase, resulting in decreased production of dopamine[39] (Figure 14-6). The displaced tyrosine may be decarboxylated to tyramine and then converted to the false neurotransmitter octapamine. Accumulated tyrosine also competes for dopamine β-oxidase and reduces the formation of norepinephrine. Phenylalanine and tryptophan in the CNS ultimately are converted to phenylethanolamine and serotonin, a false neurotransmitter and a neuroinhibitor, respectively. Tryptophan also is metabolized to serotonin and oxindole, which has a strong sedative effect.[32]

Consistent with this theory are the observationsof increased serum concentrations of AAAs accompanied by increased cerebrospinal fluid concentrations of octopamine, serotonin, and phenylethanolamine in patients with HE.[37] However, octapamine alone cannot induce encephalopathy, the plasma BCAA:AAA ratio correlates poorly with HE in human beings,[40] and controlled clinical trials of oral or intravenous BCAA therapy do not indicate consistent amelioration of signs of HE.[39]

A recently popular theory regarding the pathogenesis of HE involves augmented activity of inhibitory neurotransmitter systems, GABA-benzodiazepine and serotonin, and depression of the function of the excitatory glutamatergic system.[32] When released from presynaptic neurons, GABA binds to specific receptors on postsynaptic neurons, resulting in increased chloride ion conductance across the postsynaptic neural membrane, membrane hyperpolarization, and generation of an inhibitory postsynaptic potential.[41] The GABA receptor is a chloride ionophore supramolecular complex that has interactive binding sites for three classes of synergistic ligands: GABA and agonists, benzodiazepines, and barbiturates.[24,42] The binding of benzodiazepine or a barbiturate on its binding site of the GABA receptor potentiates GABA-induced sedation. The GABA hypothesis of HE originally was based on a series of observations using a model of HE in rabbits in which increased GABA-like activity was identified in the serum and cerebrospinal fluid along with an increased density of GABA receptors.[41] Increased brain levels of natural benzodiazepines probably constitute one mechanism for the increased GABAergic tone in HE.[32] Ammonia, which acts synergistically with natural benzodiazepines, also may enhance GABAergic neurotransmission. Agonists of benzodiazepine increase the frequency of GABA-induced chloride channel openings, and barbiturates lengthen the average time that channels are open.[43] Results of studies using electrophysiologic and in vitro techniques to study an animal model of HE provide strong evidence for a functional increase in 960
GABAergic tone that is mediated allosterically through the benzodiazepine receptor by an endogenous 961

diazepam-like substance.[44,45] Clinical studies that showed improved consciousness and reduced electroencephalogram changes of HE in patients treated with the benzodiazepine receptor antagonist flumazenil support this suggestion.[46] Recent evidence also points to zinc deficiency, which is important for the urea cycle, in the pathogenesis of HE.[32]

Figure 14-6 Role of aromatic amino acids in the brain in hepatic encephalopathy. Aromatic amino acids (tryptophan, tyrosine, phenylalanine) enter the CNS, where they are metabolized, altering the balance of neurotransmitters. True neurotransmitters (dopamine, norepinephrine) decrease *(down arrow)*, whereas false neurotransmitters (octopamine, phenylethanolamine) increase *(up arrow)*. The net effect is increased neuronal inhibition and reduced neuronal excitation.



14.2.3.2.3

Diagnosis

The diagnosis of HE is based on neurologic signs of cerebral dysfunction in a horse with physical examination and laboratory findings compatible with liver disease (see Diagnosis and Laboratory Findings of Hepatic Insufficiency). *One should exclude other possible causes for the neurologic signs because no specific features of HEallow one to distinguish this syndrome definitively from other encephalopathies*. A partial list of conditions to be ruled out includes trauma, viral encephalomyelitis, rabies, moldy corn toxicity (leukoencephalomalacia), brain abscess, equine protozoal myeloencephalitis, parasite larval migrans, blister beetle toxicosis, organophosphate toxicity, nigropallidal encephalomalacia, botulism, fluphenazine or other sedative overdose, and heavy metal toxicosis. Many of these conditions have other characteristic clinical signs, the absence of which would exclude them from the differential diagnosis. One carefully should determine access to potential toxins or drugs from the history.

One should perform serum electrolyte testing, including calcium, and obtain creatinine values and a complete blood count to aid in ruling out other encephalopathies. Serologic testing for the viral encephalitides and toxicologic screening for organophosphates and heavy metals may be appropriate. A lumbar spinal tap for cerebrospinal fluid analysis may be indicated if other causes of encephalopathy are highly suspect. The cerebrospinal fluid is normal in horses with HE. In human beings, electroencephalogram changes of symmetric generalized slowing of cerebral electrical activity are sensitive indicators of HE but are not specific for this disorder because other metabolic encephalopathies can cause 961
similar abnormalities.[23,25] Visual evoked potentials are superior to conventional electroencephalograms in 962
terms of specificity and ease of quantitation.[47] An average visual evoked potential reflects the pattern and magnitude of postsynaptic neuronal activity evoked by a visual afferent stimulus. Hepatoencephalopathy in human beings is attended by a distinctively abnormal visual evoked potential trace; however, this testing would be technically difficult in horses and has not been explored. As a general rule, the brain shows no definite light or electron microscopic structural changes; however, some patients with hepatic cirrhosis and portosystemic shunts have an increase in the number and size of astrocytes (Alzheimer's type II) in the gray matter of the cerebrum and cerebellum.[24] These changes appear to be reversible and specific for portosystemic shunting of blood. The relevance of these changes, if any, to behavioral dysfunction of HE is unknown.

14.2.3.3

Icterus

Icterus, or *jaundice*, is caused by *hyperbilirubinemia* with subsequent deposition of the pigment in tissues causing yellow discoloration. Icterus is most apparent in nonpigmented skin; mucous membranes, especially the vulvar mucosa; and the sclerae. Approximately 10% to 15% of horses normally have slightly yellow sclerae.[20] Disease states that result in hyperbilirubinemia can be categorized as follows: increased production of bilirubin, impaired hepatic uptake or conjugation of bilirubin, and impaired excretion of bilirubin.[17] Increased production of bilirubin occurs with hemolysis, intravascular and extravascular, and following reabsorption of erythrocytes after massive intracorporeal hemorrhage. This form of hyperbilirubinemia, often called *hemolytic* or *prehepatic icterus*, occurs despite a normally functioning liver, because the rate of bilirubin production by the reticuloendothelial system temporarily exceeds the ability of the liver to conjugate and excrete. Classically, this form of icterus is caused by the increased concentration of unconjugated bilirubin in the blood. However, on occasion the concentration of conjugated bilirubin also mildly increases in the blood because of hepatic spillover when the liver processes the excessive bilirubin or the enterohepatic

circulation reabsorbs it. The presence and intensity of hemolytic icterus are determined by the rate and extent of erythrocyte destruction and the rate of uptake of bilirubin by the liver.

Impaired uptake and conjugation of bilirubin also result in increased blood levels of unconjugated bilirubin with subsequent icterus. This form of icterus is referred to as *retention* or *hepatic icterus* and is the most common form in horses with liver disease, usually the result of acute hepatocellular disease.[12,17,20] In horses the presence of icterus is highly inconsistent with chronic hepatocellular disease.[11,22] In addition to hepatocellular disease, certain drugs, anorexia, or prematurity can impede bilirubin uptake and conjugation by hepatocytes, despite an otherwise normally functioning liver.[4,11,12,17] Steroids can inhibit bilirubin uptake in all species. Heparin administration to horses sometimes results in icterus and is believed to be caused in part by impaired uptake of bilirubin by hepatocytes.[11] Anorexia in horses causes variable degrees of hyperbilirubinemia and may be related to the half-life of ligandin.[11,20] Ligandin is the intrahepatic protein responsible for extracting unconjugated bilirubin from albumin in the sinusoidal blood. The half-life of ligandin is short (days), and starvation in other species reduces the store of ligandin in the hepatocytes, thus impeding bilirubin uptake.[4] Premature and neonatal foals are also more susceptible to retention icterus in the absence of hepatic disease. The cause of icterus in equine neonates presumably is lower hepatocellular ligandin concentrations compared with the adult.[48] In human beings, inherited or congenital deficiencies in enzymes responsible for conjugation (bilirubin-uridine diphosphate glucuronyl transferase) may result in intermittent or persistent icterus (Gilbert's syndrome or Crigler-Najjar syndrome type II) that often is not recognized until the patient is several years of age. The icterus occurs without other clinical or laboratory evidence of liver diease.[20] Persistent hyperbilirubinemia without anorexia, hemolysis, or evidence of acquired liver disease was reported in an otherwise healthy 4-year-old Thoroughbred gelding.[49] Conjugated bilirubin concentrations were normal, but total serum bilirubin concentrations ranged from 9.0to 12.3 mg/dl during a 2½-year monitoring period. The case most closely resembled Gilbert's syndrome.

If the excretion of conjugated bilirubin into the biliary tract is impeded, *regurgitation icterus* occurs.[17] Blockage of bile flow with resultant regurgitationicterus can accompany cholangitis, hepatitis, obstructive cholelithiasis, neoplastic infiltration, fibrosis, or hyperplasia of the biliary tract. Because conjugated bilirubin is water soluble, this form of icterus may be accompanied by bilirubinuria.

In hepatocellular disease, icterus most often results from a combined increase in unconjugated and conjugated bilirubin.[17] Of the two fractions the majority of the increase in the total bilirubin is from unconjugated bilirubin. Increases in the conjugated fraction greater than 25%of the total usually indicate hepatocellular disease, and increases greater than 30% usually indicate cholestasis.[12]

14.2.3.4 Weight Loss

Significant weight loss and failure to thrive are most consistently present during chronic hepatic insufficiency. However, chronic liver disease may be present without apparent weight loss. Weight loss is caused by anorexia and the loss of normal hepatocellular metabolic activities. 962

963

14.2.3.5 Hepatogenic Photosensitization

Photosensitization refers to abnormally heightened reactivity of the skin to ultraviolet sunlight because of the increased blood concentration of a photodynamic agent. In the case of hepatogenic photosensitization, the

photodynamic agent is *phylloerythrin*. Phylloerythrin normally is formed in the gastrointestinal tract as a result of bacterial degradation of chlorophyll and is absorbed into the general circulation, conjugated, and excretedby the liver.[50] During hepatic insufficiency, the blood concentrations of this photodynamic agent increase. Subsequent exposure of phylloerythrin to ultraviolet light causes activation of electrons within the molecule to an excited state, with resultant free radical formation. The local production of free radicals causes cell membrane damage and necrosis. Unpigmented areas absorb ultraviolet light most efficiently, thus the lesions of photosensitization are restricted to white skin. The skin first appears erythematous and edematous. Pruritus, pain, vesiculation, ulceration, necrosis, and sloughing may ensue.

14.2.3.6 Colic, Diarrhea, Tenesmus, Ascites, and Steatorrhea

Abdominal pain associated with acute hepatocellular disease may result from acute hepatic swelling or biliary obstruction (cholelithiasis).[4,51] Signs of anterior abdominal pain include anorexia, bruxism, sitting like a dog, recumbency, and rolling up onto the dorsum. Palpation over the last few ribs (especially on the right) or immediately caudal to the rib also may elicit a pain response. Alterations in intestinal motility also may cause concurrent signs ofcolic with liver disease. McGorum, Murphy, Love, et al.[22] recently reported that 10 of 25 horses with liver disease and signs of colic had clinically significant gastric impactions. Of the horses with gastric impactions, seven also had signs of HE and none of these horses survived.

Diarrhea infrequently may accompany chronic hepatic insufficiency in horses.[52] Alterations in the intestinal microflora, portal hypertension, and deficiency of bile acids may be involved in the pathogenesis.[4] Though uncommon in horses, portal hypertension can lead to increased hydrostatic and oncotic pressure in the intestinal mucosa, with resultant water and protein loss into the lumen of the bowel and the peritoneal cavity (ascites). Tenesmus may result from constipation but also has been reported to be a sign of hepatoencephalopathy.[22]

Decreased excretion of bile may result in lipid malabsorption and excessive amounts of fat in the feces, or *steatorrhea*,[4] which subsequently may cause osmotic diarrhea. Because the normal equine diet is low in fat, steatorrhea is rare in horses. Chronic cholestasis may cause clay-colored feces because of lack of fecal urobilinogen and stercobilin. This coloration rarely is observed in adult herbivores, because the normal fecal color is generated primarily by plant chlorophylls and not by bilirubin metabolites.[12]

14.2.3.7 Hemorrhagic Diathesis

Because the liver is responsible for synthesizing numerous factors involved in coagulation and fibrinolysis, abnormal hemostasis may be a sequela to hepatic insufficiency. Clinical signs may vary from petechial or ecchymotic hemorrhages to hemorrhage after trauma or venipuncture to spontaneous hemorrhage (epistaxis, melena, hemoptysis, hematuria, or hematomas).[4,12,17,53,54] Especially sensitive to hepatic disease is the synthesis of fibrinogen and the vitamin K–dependent factors (II, VII, IX, X, and protein C), which have short half-lives. Factor VII has a half-life of only 4 to 5 hours. Other vitamin K–dependent factors and fibrinogen have half-lives in the range of 4 to 5 days. Because vitamin K is fat soluble and requires bile acidsfor proper absorption from the intestinal tract, vitamin K–dependent factors are affected particularly during hepatic insufficiency when bile excretion is decreased.

During hepatic insufficiency, the synthesis of protein C and antithrombin III may be altered. Decreased plasma concentrations of these two anticoagulants would resultin uncontrolled clot formation and

consumption of other coagulation factors. In chronic hepatic disease the plasma concentration of protein C is normal or decreased; however, antithrombin III may be normal, increased, or decreased. Pregnant women with fatty livers have decreased antithrombin III activity, but patients with biliary cirrhosis or biliary obstruction have increased antithrombin III activity.[53] Horses with liver disease have increased antithrombin III activity and theoretically should tend to bleed.[55] Alterations in the factors controlling fibrinolysis vary in chronic liver disease.[53] Conditions that promote fibrinolysis—such as increased plasminogen and plasminogen activator, or decreased plasminogen activator inhibitor, α_2-antiplasmin, and α_2-macroglobulin—result in bleeding tendencies. Conditions that aid thrombus formation, such as decreased plasminogen, further promote consumptive coagulopathy. The fibrinolytic factors have not been evaluated in horses with liver disease.

Finally, the liver plays an important role in balancing normal hemostasis by Kupffer's cell removal of activated coagulation factors and fibrin degradation products from the general circulation.[53] Failure to remove activated coagulation factors further promotes coagulation, and fibrin degradation products interfere with platelet function and fibrin clot formation.

14.2.3.8 Fever

Horses with hepatic abscesses, acute hepatitis, chronic active hepatitis, obstructive cholelithiasis, fatty liver failure, or neoplasia may have constant or intermittent fevers.[51,56–61] 963

964

14.2.3.9 Hemolysis

Hemolysis is a rarely seen but grave prognostic indicator of fulminant hepatic failure in horses.[19] The exact cause of hemolysis is not known but is believed to result from increased erythrocyte fragility.

14.2.3.10 Pruritus and Seborrhea

Retention of bile acids and accumulation in the skin may cause pruritus and seborrhea. This finding is reported rarely for horses.[19,62]

14.2.3.11 Edema

Hypoalbuminemia and water retention can occur with chronic liver failure and may result in dependent edema. Because the half-life of albumin is long (19 to 20 days) in the horse, edema is a rare clinical sign.[63] Ponies with hyperlipemia may develop dependent abdominal edema following vascular thrombosis.[60] Dependent abdominal edema also may form if significant portal hypertension and ascites exist.

14.2.3.12 Endotoxemia

The Kupffer's cell plays an important role in removing bacterial endotoxin that normally is absorbed from the lumen of the intestinal tract and carried to the liver via the portal circulation.[16] Failure of Kupffer's cell phagocytosis of endotoxin may result in clinical and laboratory evidence of endotoxemia.

14.2.3.13 Polydipsia, Polyuria, and the Hepatorenal Syndrome

Alterations in renal function, including deranged sodium concentrations, impaired water excretion, and urine concentrating ability, may accompany severe liver disease.[4,64] Sodium retention results from increased blood aldosterone concentrations caused by failure of hepatic biotransformation and a decrease in the effective circulating blood volume resulting from portal hypertension and hypoalbuminemia. Sodium retention raises the osmolality of the extracellular fluid, thereby stimulating the thirst center. Polydipsia has been reported in horses with chronic liver disease.[65,66] Despite the potential increase in exchangeable sodium, the serum sodium concentration is usually normal or decreased, resulting from superimposed water retention. The mechanism for water retention is multifactorial, but increased antidiuretic hormone, reduced effective circulating volume, and altered renal prostaglandin synthesis most likely are involved.[64] The urine concentrating ability is impaired sometimes because of reduced medullary interstitial urea, the net effect being polyuria or isosthenuria or both.

Hepatorenal syndrome is characterized by acute azotemia and anuria and may occur in ponies with hyperlipemia and hepatic lipidosis (see Hyperlipemia and Hepatic Lipidosis). The pathogenesis is obscure, but speculative causes include reduced effective circulating volume, decreased hepatic inactivation of renin, and endotoxemia.[64]

14.2.4 DIAGNOSIS AND LABORATORY FINDINGSOF HEPATIC INSUFFICIENCY

Historical information, as discussed under Specific Hepatic Diseases, may be useful in diagnosing certain types of hepatic insufficiency. The definitive diagnosis of hepatic disease in horses is confounded by nonspecific clinical signs and variable laboratory findings. Paramount to the laboratory diagnosis of hepatic insufficiency in horses is knowledge of the sensitivity and specificity of the tests (Table 14-2). Because massive hepatic disease must be present before alterations are apparent with some laboratory tests and because different liver functions are altered variably by disease, the specificity of the laboratory diagnosis of hepatic disease increases with the magnitudeof abnormal findings. Laboratory findings also may be useful for therapeutic and prognostic considerations.

14.2.4.1 Evaluation of Bilirubin

Serum bilirubin concentration is not a sensitive indicator of liver disease in horses. In one report on serum biochemical changes in horses with liver disease, only one fourth of the horses had increased serum bilirubin concentrations.[22] The *total bilirubin* concentration in the blood, as determined by the van den Bergh test, is a combination of unconjugated and conjugated bilirubin. Because the diagnostic value of the bilirubin concentration, when used for evaluation of hepatic disease, depends on which subfraction is increased, one must determine the concentrations of unconjugated and conjugated bilirubin.

The serum bilirubin concentration is stable for several days, if one protects the sample from sunlight. One first determines the total bilirubin concentration in a chromogenic assay by reaction for 30 minutes with a diazo reagent (sulfanilic acid and sodium nitrite) and methyl alcohol.[12] One similarly determines *conjugated* or *direct reacting bilirubin* over 5 minutes without the additionof methyl alcohol. One then determines the amount of *unconjugated bilirubin* by the difference between the total bilirubin concentration and the direct reacting bilirubin. Because one determines the unconjugated fraction arithmetically, the fraction is called

appropriately *indirect reacting bilirubin*. In normal horses the total bilirubin concentration ranges from 0.2 to 5.0 mg/dl (3.4 to 85.5 μmol/L) with conjugated bilirubin ranging from 0 to 0.4 mg/dl (0 to 6.8 μmol/L).[17] As discussed previously, increases in the unconjugated bilirubin fraction may occur without hepatic disease. 964
Hemolysis, anorexia, intestinal obstruction, cardiac insufficiency, Gilbert's syndrome, and the administration 965
of certain drugs (steroids, heparin, halothane) may cause an increasein the unconjugated bilirubin concentration.[11] If the unconjugated bilirubin concentration is increased, one should evaluate the erythron concurrently to rule out hemolysis as the causative factor. Hemolysis may cause the unconjugated bilirubin concentration to rise as high as 80 mg/dl (1368 μmol/L). Complete anorexia can cause an increase in the unconjugated bilirubin concentration within 12 hours; however, the concentration is unlikely to rise to greater than 6 to 8 mg/dl (102.6to 136.8 μmol/L) in horses suffering purely from anorexia[12]; however, values as high as 10.5 mg/dl have been reported in anorexic horses.[62] Finally, one must consider the age of the horse and concurrent drug therapy. Neonates normally have more unconjugated bilirubin than adults. The higher bilirubin concentration in foals most likely is caused by the turnover of fetal hemoglobin to adult hemoglobin and the deficiency of liver-binding and conjugating enzymes compared with the adult.[48] In the absence of liver disease, concurrent prematurity or illness can increase the unconjugated bilirubin fraction in foals further.

TABLE 14-2 Clinical Pathology of Liver Disease in Horses

TEST	ABERRATION	NORMAL VALUE
SPECIFIC INDICATORS OF LIVER DISEASE		
Serum sorbitol dehydrogenase	Increases	<8 units/L
Serum γ-glutamyl transferase	Increases	<25 units/L
Serum bile acids concentration	Increases	<15 mol/L
Arginase	Increases	
Glutamate dehydrogenase	Increases	
Direct bilirubin	>25% of total	0–0.4 mg/dl (0–6.8 μmol/L)
Ammonia	Increases	Laboratory dependent
Bromosulphthalein half-life	Prolonged	2.8 ± 0.5 minutes
Branched-chain amino acid to aromatic amino acid ratio	Decreases	3.5–4.5
Urine bilirubin	Increases	
NONSPECIFIC INDICATORS OF LIVER DISEASE		
Total bilirubin	Increases	
Indirect bilirubin	Increases	
Lactate dehydrogenase-5	Increases	
Aspartate aminotransferase	Increases	
Alanine aminotransferase	Increases	
Alkaline phosphatase	Increases	
Blood urea nitrogen	Decreases	
Globulins	Increases	
Albumin	Decreases	
Glucose	Decreases	
Prothrombin time	Prolonged	
Activated partial thromboplastin time	Prolonged	
Triglyceride	Increases	
White blood cell count	Increases with infection or inflammation; decreases with endotoxemia	

Keeping the foregoing limitations of interpretationin mind, increases in the unconjugated bilirubin fraction in horses with hepatic disease are most likely to occur with acute hepatocellular disease.[11,12,17] Rarely does the unconjugated bilirubin fraction in acute hepatic disease exceed 25 mg/dl (427.5 μmol/L).[12] An increase in the

bilirubin concentration may indicate hepatic disease but not necessarily hepatic failure. Furthermore, a normal bilirubin value, as commonly occurs in chronic hepatic disease, does not necessarily preclude the diagnosis of hepatic insufficiency.

An increase in the conjugated bilirubin fraction in horses more reliably indicates hepatic disease.[11,12,17] If the conjugated bilirubin concentration is greater than 25% of the total bilirubin value, one should suspect hepatocellular disease. If the conjugated bilirubin concentration is greater than 30% of the total value, one should suspect cholestasis.[12] Conjugated bilirubin is water soluble and detectable in the urine of horses only if blood concentrations sufficiently increase to surpass the renal threshold, thus when urine tests positive forthe presence of bilirubin, one should suspect cholestatic disease. Urine dipstick analysis is less sensitive than 965
analysis with a diazo tablet. One may detect urobilinogen by dipstick analysis in normal horse urine, and its 966
presence indicates a patent bile duct.[13] Because urobilinogen is highly unstable, one must determine the concentration in a fresh urine sample. Dilute or acidic urine may interfere with accurate determination of urobilinogen. Reagent strips are not sensitive enoughto detect the absence of urobilinogen: one must use Ehrlich's reagent. The absence of urobilinogen doesnot necessarily indicate liver disease but may be compatible with failure of excretion of bilirubin into the intestine, biliary obstruction, failure of intestinal bacterial reduction (diarrhea, overuse of oral antimicrobials), or failure to reabsorb it from the ileum. Increased concentrations of urobilinogen in the urine may be caused by the increased production of urobilinogen by intestinal bacteria, failure of the liver to remove it from the enterohepatic circulation, portosystemic shunting, or spillover following severe hemolysis.[4]

14.2.4.2 Serum Bile Acid Concentration

The normal liver removes greater than 90% of bile acids from the enterohepatic circulation. Thus the blood concentration of bile acids may be increased with liver disease, and quantitation provides an excellent screen of liver failure and essentially has replaced foreign dye clearance (e.g., Bromosulphthalein, or BSP) as a functional test of the liver.[11,66,67] Serum bile acids are stable for at least1 month if stored at −20° C and are measured by radioimmunoassay or by an enzymatic colorimetric method. The concentration of total serum bile acids is not affected by short-term fasting (<14 hours) but may be increased by more prolonged fasting.[68] The composition of serum bile acids varies greatly among normal horses, though the major serum bile acids are ursodeoxycholic acid, chenodeoxycholic acid, and deoxycholic acid.[69] Reported normal mean values for horses and ponies as determined by radioimmunoassay are 8.2 ± 1.6 μmol/L (n = 9)[66] and 5.3 ± 6.5 μmol/L (n = 51),[67] respectively, and 5.0 to 28.0 μmol/L[69] by the colorimetric method. Increased serum bile acid concentrations are highly specific for the presence of liver disease (may increase within 24 to48 hours after onset of hepatic disease) but are not specific for the type of liver disease.[11,70] Because bile acids are 90% restricted to the enterohepatic circulation, increases in the blood may result from shunting or decreased blood flow to the liver (first pass effect), failure of the liver to remove bile acids from the enterohepatic circulation, failure of the hepatocytes to conjugate the bile acids for excretion, or failure of excretion with subsequent regurgitation of the bile acids into the blood (biliary obstruction). Increases in the primary (nondegraded) bile acids cholate and chenodeoxycholate account for most of the increase in total serum bile acids concentration in horses with liver disease. In relation to the severity of liver disease, a significant shift in composition of serum bile acid profile from taurocholate to free unconjugated cholate also occurs. This finding suggests that hepatocellular excretion, and not resorption, is the most sensitive step in the enterohepatic circulation of bile acids in horses.[69]

Fasting for longer than 3 days in horses caused an increase in the serum bile acid concentration of 3 times over baseline values. Ligation of the bile duct caused a sixfold increase in serum bile acid concentration compared with fasted horses. Carbon tetrachloride toxicity resulted in a threefold increase compared with fasted horses.[68] Concentrations of serum bile acids greater than 50 μmol/L in horses with pyrrolizidine toxicosis were associated with a grave prognosis.[66] A value less than20 μmol/L appears to be a good predictor in ruling out significant functional liver disease and should be included in the evaluation of horses suspected to have hepatic disease. Serum bile acid concentrations greater than 20 μmol/L appear to indicate chronic liver disease but are less effective in detecting acute hepatic disease.[67] Bile acid concentrations are highest in biliary obstructive diseases and portosystemic shunts.

14.2.4.3 Tests of Protein Synthesis

The blood concentrations of protein or amino acids relate not only to the rate of synthesis by the liver but also to their half-life in the circulation. The half-life of albumin in horses is long (19 to 20 days), thus a decrease in the albumin concentration is rarely detectable until greater than 80% of the liver mass is lost for more than 3 weeks.[12,17,22,63] For the total serum protein to decrease below 5 g/dl (50 g/L) in chronic liver disease is unusual.[16] Hypoalbuminemia is a nonspecific finding in chronic liver disease, for it may occur following endoparasitism, nephrosis, malnutrition, malabsorption, circulatory failure, and many other chronic diseases.[20,63]

The globulin fraction often is increased in chronic hepatic disease because of decreased Kupffer's cell mass. Loss of Kupffer's cell function may result in wider dissemination of enteric-derived foreign antigens. Plasma cells respond to the general increased antigen load, resulting in polyclonal gammopathy.[4,9,12] Although the globulin fraction may be increased, it is a nonspecific finding with chronic hepatic disease, because polyclonal gammopathy can occur following numerous chronic diseases. A decreased serum albumin concentration concurrent with an increased globulin concentration in chronic hepatic disease causes the total plasma protein or serum protein to appear normal. Thus serum protein fractionation is paramount. Protein electrophoresis most accurately determines fractionation of the components making up the total serum protein.[9] 966

967

The blood concentration of amino acids may be increased following acute hepatocellular necrosis or during protein catabolic states such as illness or starvation in response to insulin or glucagon.[4] Fractionation of the blood amino acids and determination of the BCAA:AAA ratio rarely is done in clinical practice but is more useful than evaluating either fraction separately (see Hepatic Encephalopathy). Decreases in this ratio indicate hepatic insufficiency. The risk of clinical signs of HE may be projected from the BCAA:AAA (phenylalanine, tyrosine) ratio. A normal ratio falls between 3.5 and 4.5. The risk of HE is low, medium, or high if the ratio is 3.0 to 3.5, 2.5 to 3.0, and less than 2.5, respectively.[38]

Because the liver is primarily responsible for removing ammonia from the circulation and converting it to urea for renal excretion, increases in the blood ammonia concentration or a decrease in the BUN concentration(<9 mg/dl; 6.43 mmol/L) may indicate chronic hepatocellular disease.[16,17,22] Daily blood ammonia levels vary widely in normal horses.[21] The compounding effects of ammonia-generating and urea-using bacteria in the gastrointestinal tract, ammonia generation with blood storage, and the effects of the ration may account partly for these fluctuations. One can refrigerate whole blood in EDTA for up to 6 hours without a significant increase in ammonia content.[71] One can evaluate the effect of the ration and handling by concurrently determining the blood ammonia concentration of a stable mate receiving a similar ration. Oral ammonia

challenge tests have not been evaluated fully in horses; however, the sensitivity of the oral challenge test may be decreased because of the effect of enteric bacteria. Normal values for ammonia vary among laboratories but have been reported in the range of 13 to 108 μg/dl (7.63 to 63.42 μmol/L).[19]

No correlation exists between the blood ammonia concentration and the severity of liver disease in horses, but increased blood ammonia concentration significantly is correlated with the presence of liver disease and with hepatoencephalopathy.[21,22] Although hyperammonemia appears to be a sensitive indicator of liver disease in the horse, it is not specific for liver disease. Encephalopathy associated with hyperammonemia without concurrent evidence of liver disease has been reported in horseswith acute gastrointestinal disease.[72,73] Hyperammonemia also has been reported as a fatal heritable disorder in Morgan foals and is believed to be caused by a defective mitochondrial transporter protein involved in urea synthesis.[74] The syndrome may be accompanied by mild to moderate increases in serum liver enzyme activities.

Because the liver is also responsible for the synthesis of certain coagulation factors, evaluation of hemostatic function may be useful. Changes in hemostatic function values are not specific for liver disease and must be evaluated in light of the other laboratory findings. The vitamin K–dependent factor with the shortest half-life is factor VII, thus abnormalities frequently are observed first in the *prothrombin time (PT)*.[21] However, adequate evaluation of hemostatic function necessitates determination of the *activated partial thromboplastin time (APTT)*, the *fibrinogen* and *fibrin degradation products* concentrations, and a platelet count. In one retrospective clinical review, almost half of the horses with liver disease had an abnormally prolonged PT or APTT.[22] Typically, a 50% to 70% decrease in the blood concentration of the coagulation factors is necessary before a change in these clotting time–based assays is detectable.[17] Daily variation in the normal values for clotting times also hinders accurate detection of the abnormal. The clotting times may be standardized more appropriately if one determines a clotting assay concurrently on a normal horse. If the ratio of clotting time (PT or APTT) of the patient with suspected hepatic disease to the normal value of the horse is greater than 1.3, one may interpret the test as abnormal.[75] The sensitivity of coagulation factor deficiency during hepatic insufficiency may be increased by diluting the plasma[76] or by determiningthe concentration of specific factors by clot-based, chromogenic, or radioimmunologic assays. These latter assays are not widely available.

One cannot detect hypofibrinogenemia accurately by the heat block precipitation method, the most common method for determining the plasma fibrinogen concentration.[9] A clotting assay using thrombin more accurately determines the fibrinogen concentration. Fibrinogen concentrations less than 100 mg/dl (1 g/L) indicate decreased production or increased consumption. The fibrin degradation product concentration, as determined by latex agglutination, may be increased during hepatic insufficiency because of decreased removal by Kupffer's cells. Concentrations of fibrin degradation products greater than 16 μg/dl indicate increased production or reduced removal. The plasma concentration of several factors acting as anticoagulants or involved in fibrinolysis also may be altered in chronic liver failure (see Hemorrhagic Diathesis). Tests for these factors are limited primarily to academic and research institutions.

Thrombocytopenia with associated petechiae or nasal mucosal bleeding has been reported in horses with liver disease, and thus in suspected cases of liver disease, one also should evaluate platelet counts before using invasive diagnostic or therapeutic techniques.[21]

14.2.4.4 Tests of Carbohydrate Metabolism

Changes in the blood glucose concentration rarely occur in horses with liver insufficiency.[16,22] Hyperglycemia may occur with stress-associated catecholamine and glucocorticoid release. Hypoglycemia (glucose <60 mg/ 967
dl;3.33 mmol/L) may occur in acute massive hepatic failure but is more likely in chronic liver disease as 968
anorexia progresses, glycogen stores are depleted, and gluconeogenesis and glycolysis are impaired by increased glucagon concentrations. If one administers glucose, often blood glucose levels remain abnormally increased, indicating tissue insulin resistance.[77] Insulin receptor number and binding affinity for insulin have been found to be diminished in human beings with chronic liver disease. Changes in the blood glucose concentration are not specific for liver disease and must be evaluated in the light of the other laboratory findings.

14.2.4.5 Tests of Lipid Metabolism

The concentration of blood triglycerides may become increased during hepatic insufficiency because of increased mobilization from adipose tissue to support energy-requiring processes and a decreased clearance by the liver.[4,12] In contrast, the VLDL and esterified cholesterol blood concentrations may be decreased because of failure of liver synthesis. Compared with other species, Equidae are thought to possess a greater clearance capacity for triglycerides and a greater hepatic exporting capacity for VLDLs. Thus changes in the blood VLDL, esterified cholesterol, or triglyceride concentrations occur rarely in horses.[20] An exception to this is the significant increase in blood triglyceride levels that occurs with hyperlipidemia syndrome in ponies and miniature horses (see Hyperlipemia and Hepatic Lipidosis). Because blood lipid concentrations may be altered by nonhepatic diseases, these tests are neither sensitive nor specific for liver disease in horses.[12] The blood cholesterol and triglyceride concentrations are normally higher in neonates compared with adults.[48]

Increased mobilization of triglycerides and fatty acid oxidation by the liver may result in increased production of *ketone bodies*, acetoacetate and β-hydroxybutyric acid.[10] Although the peripheral tissues may use ketone bodies, these compounds are weak acids and increased levels in the blood may result in ketoacidosis. The pathway for ketone formation is developed poorly in horses, thus ketoacidosis is not common.[20] One should suspect ketoacidosis in horses that are acidemic and have an abnormally high anion gap. One may quantitate ketones in the blood or urine. Because the renal thresholdof ketone bodies is low, ketonuria usually precedes ketonemia. Routine urine dipsticks only detect acetoacetate.[12]

14.2.4.6 Liver Enzymes

Acute hepatocellular necrosis or changes in hepatocyte membrane permeability result in the release of soluble cytosolic enzymes into the sinusoidal blood. Thus increased blood activity of these cytosolic enzymes may indicate active hepatic disease. One must exercise caution when evaluating increases in these enzymes because not all are liver-specific. Furthermore, some of these hepatocellular enzymes may be increased because of induction by drugs. Most of these enzymes are quantitated colorimetrically, thus hemolysis or lipemia may interfere with accurate evaluation. Furthermore, wide variation in values can exist because of age differences, stage of hepatic disease, and laboratory methodology. In horses the following cytosolic enzymes are liver-specific and are not inducible: sorbitol dehydrogenase (iditol dehydrogenase), arginase, ornithine carbamoyltransferase, and glutamate dehydrogenase.[12,17] Although increases in these enzymes in the blood

are highly specific for heptocellular disease, they are not specific for the type of disease. Significant increases occur following acute hepatic necrosis. Mild increases in these enzymes may occur following hepatic hypoxemia or toxemia resultingfrom endotoxemia, septicemia, transient intestinal disease, hyperthermia, or certain drugs (benzimidazole anthelmintics).[12,16,17]

Sorbitol dehydrogenase (SDH) or iditol dehydrogenase has been used widely to evaluate acute liver disease in horses.[16,48,78] The short half-life of this liver cytosolic enzyme makes it ideal for evaluating acute ongoing disease, for values usually return to baseline within 3 to5 days after a transient hepatic insult.[62] Its short half-life necessitates analysis within hours of collection. Storage of serum in the freezer (−15° C) or refrigerator results in lost of approximately 1% and 3.5%, respectively, of SDH activity per day.[79] Although mild variations exist between laboratories, the normal blood activity of SDH in horses is usually less than 8 units/L.[19] Foals 2 to 4 weeks of age may have SDH activity slightly greater than those of adult horses.[48,78] Increases in SDH have been reported after prolonged halothane anesthesia in horses.[80] *Arginase* is used in the Krebs-Henseleit cycle for urea synthesis and is found in highest activity in hepatocytes, though minute amounts also exist in renal tissue, brain, skin, testicles, and erythrocytes.[20] Increases in arginase are most indicative of acute hepatic necrosis. Like SDH, arginase has a short half-life. *Glutamate dehydrogenase* is found in hepatocytes, renal tissue, brain, muscle, and intestinal cells. Like SDH and arginase, glutamate dehydrogenase has the highest tissue activity in the liver, and increases of this enzyme in the blood can be considered specific for acute liver disease. The half-life of glutamate dehydrogenase is 14 hours.[20]

Other cytosolic enzymes include aspartate aminotransferase, alkaline phosphatase, lactate dehydrogenase, alanine aminotransferase, and isocitrate dehydrogenase. These enzymes also are found with high activity in other tissues or are inducible. Thus increases in these enzymes are *not specific* for liver disease in horses. 968
Because some of these enzymes frequently are reported in equine biochemical profiles, they may serve as a 969
crude indicator of liver disease; however, one must recognize the limitations of their usefulness.

Aspartate aminotransferase (AST), formerly glutamic-oxaloacetic transaminase, is a cytosolic- and mitochondrial-bound enzyme that catalyzes the reaction responsiblefor aspartate biosynthesis from carbohydrates. Basically, all cells contain AST, but liver and skeletal muscle cells contain the highest activity. Cardiac muscle, erythrocytes, intestinal cells, and the kidney also are sources of AST. Hemolysis and lipemia falsely increase the value of AST.[17] Increases most frequently are associated with muscle damage but may occur following acute hepatic necrosis. Often the AST activity is normal in chronic hepatic disease.[16] The half-life of AST is long, and thus the blood activity may take greater than 2 weeks to decrease following acute hepatic disease. The AST value is most useful when analyzed with other tissue-specific enzymes. For instance, if a muscle-specific enzyme, such as creatine kinase, also is increased, an increase in AST most likely has its origin in muscle. Serial AST and SDH valuescan be useful for determining ongoing hepatic disease. If the SDH and AST values were increased initially but subsequent evaluation reveals a normal or decreasing SDH and elevated AST, then a favorable prognosis is indicated, because hepatic necrosis is most likely subsiding. The normal serum activity of AST is 98 to 278 units/L.[19] *Isocitrate dehydrogenase* has a distribution similar to AST.

Alanine aminotransferase, formerly glutamic-pyruvic transaminase, is responsible for alanine synthesis from carbohydrates. Increases may be evident with acute hepatic disease, but myositis also increases blood levels. Hemolysis falsely increases the value of this enzyme, and microsomal enzyme inducers (i.e., glucocorticoids) increase its production and release in the absence of liver disease. This enzyme is not useful for predicting liver disease in horses.[17]

Alkaline phosphatase (ALP) catalyzes the hydrolysisof monophosphate esters. This enzyme is bound to the mitochondrial membrane and thus does not leak into the blood with changes in cell membrane permeability or necrosis. Increases in the blood activity of this enzyme follow induction.[17] Cholestasis and certain drugs, including glucocorticoids, primidone, and phenobarbital, induce production and release of ALP. The ALP value most likely is increased in chronic or cholestatic liver diseases rather than acute or hepatocellular disease. Other tissues besides the liver contain ALP, including bone, intestine, kidney, placenta, and leukocytes; thus increases do not necessarily indicate cholestasis. Because of increased osteoblastic activity, foals have ALP values2 to 3 times those of adults.[20] Pregnancy, hemolysis, and gastrointestinal disease also cause increases in ALP.

Lactate dehydrogenase (LDH) is the name for five major isoenzymes located in liver, muscle, erythrocytes, intestinal cells, and renal tissue. Increases in LDH are not liver-specific unless the isoenzyme activity is determined. Isoenzyme 5 (LDH-5) is a useful indicator of acute hepatocellular disease in horses because values typically return to baseline within 4 days after a transient hepatic insult.[62,81] LDH-5 is also present in muscle, so increased serum LDH-5 activity is specific for hepatic disease if other indicators of muscle damage (i.e., creatine kinase) are normal.[82] LDH -5 is stable at room temperature for 36 hours.

γ-*Glutamyl transpeptidase* or γ-*glutamyltransferase (GGT)* is involved in glutathione metabolism and transfer of glutamyl groups.[17] γ-Glutamyl transpeptidase is associated primarily with microsomal membranes in the biliary epithelium. Cholestatis induces production and release of GGT. Renal tubule cells contain GGT, but this source is released into urine. The only other potentially significant source of GGT in the blood is pancreatic. Because pancreatic disease is rare in horses, the blood activity of GGT is considered specific for hepatic disease in horses. Some clinicians consider GGT to be the test of highest sensitivity when evaluating horses for evidence of liver disease. The half-life of GGT is approximately 3 days, and GGT is stable in serum for 2 days at room temperature or 30 days if frozen.[20] Mild increases may be evident following acute hepatocellular necrosis and may continue to rise for 1 to 2 weeks despite improvement in clinical signs.[62] Increases are more persistent in chronic disease, especially with cholestasis.[16] Foals 2 weeks to 1 month old may have greater GGT values than adults.[48,78] Normal values for GGT inadult horses typically are less than 30 units/L[19] butmay be 2 to 3 times greater in healthy donkeys, burros, and asses.[83] In chronic, nonactive hepatic fibrosis and focal hepatic disease, GGT may not be increased significantly. Increased serum GGT activity has been reported in horses with cholestasis following colonic displacement.

In summary, evaluation for liver disease in horses should include quantitation of at least SDH (or arginase) and GGT. However, one should not intrepret normal values for these liver enzymes necessarily as absence of liver disease.

14.2.4.7 Clearance of Foreign Dyes

In addition to clearance of endogenous substances from the blood, one can evaluate liver function following injection of an exogenous substance. One such exogenous substance that is removed by the liver, conjugated, and excreted into bile is BSP. Following intravenous injection of 2.2 mg BSP per kilogram body mass, one 969
determines a clearance half-life by periodically obtaining heparinized blood samples over 12 to 15 minutes. 970
One should exercise caution when injecting BSP, for it can be thrombogenic and irritating if administered peri-vascularly. One should collect blood samples for BSP quantitation from a site other than the injection site. Suggested collection times are 3, 6, 9, 12, and 15 minutes after injection. Collection of plasma at the suggested

times is not crucial; however, recording the exact time at which the samples were obtained is important to assure accurate determination of the half-life. One determines the half-life of BSP, thus the rate of extraction by the liver, by plotting the plasma concentrations against the collection times on semilog paper. The normal half-life of BSP in horses is 2.8 ± 0.5 minutes.[12]

The BSP half-life is prolonged when greater than50% of the hepatic function is lost.[12,17] The function test is useful in horses, especially to distinguish hepatoencephalopathy from other causes of abnormal behavior or cerebral signs and to test liver function in chronic liver disease when bilirubin, SDH, and GGT blood levels may be normal. Proper interpretation of the BSP half-life must take into account the state of hepatic blood and bile flow and the bilirubin and albumin concentrations. If the hepatic blood flow is decreased significantly, as may occur with hepatic congestion or portosystemic shunts, the rate of delivery of BSP to the liver will be decreased, thus the half-life of BSP in the plasma will be prolonged. Because BSP is bound to albumin for delivery to the liver, if the blood concentration of albumin is decreased greatly, a higher proportion of unbound BSP will be delivered to the hepatocytes, and the half-life of BSP will be shortened.[17] If the blood concentration of bilirubin is increased greatly, the bilirubin competes with BSP for binding sites and conjugating enzymes in the liver, thus apparently prolonging the half-life of BSP. If significant cholestasis is present, BSP excreted into the biliary tract is reabsorbed into the circulation, causing an apparent prolongation of its clearance. Thus although a BSP clearance test is useful as a test of hepatic function, one must interpret the results in light of these limitations. Furthermore, because pharmaceutical-grade BSP is no longer commercially available, this test is limited basically to academic and research institutions. Quantitation of serum bile acids concentration essentially has replaced BSP clearance as an indicator of hepatic function.

The determination of BSP clearance time has been suggested to be more useful for detecting liver disease than BSP half-life.[84] The proportionality transfer constants of clearance also have been suggested to be more useful in predicting hepatic disease than the BSP half-life alone.[85] The clearance time is the amount of dye irreversibly removed from the plasma per unit time. One gives a dose of 5 mg BSP per kilogram of body mass intravenously and collects heparinized blood samples2, 5, 10, 15, 25, and 30 minutes after injection. The BSP clearance time in fed normal horses is 10 ml/min/kg and in horses fasted 3 days is 6 ml/min/kg.[84]

The *indocyanine green* (Beckmann & Dickinson, Baltimore) clearance test has replaced the BSP clearance test in human beings.[4] Basically, the procedure and the limitations are the same as for the BSP clearance test. The indocyanine green clearance time in fed horsesis 3.5 ± 0.67 ml/min/kg and in fasted horses is 1.6 ± 0.57 ml/min/kg.[84] Although the clearance of indocyanine green is an excellent predictor of hepatic bloodflow and extraction rates, its current expense precludes routine use in horses. Another disadvantage is that quantitation requires a spectrophotometer that reads infrared wavelengths. These limitations have hindered evaluation of indocyanine green clearance times as a diagnostic test of liver insufficiency in horses.

14.2.4.8

Other Nonspecific Laboratory Findings

Increased formation and release of acidic metabolic products, including ketone bodies, lactate, pyruvate, and amino acids, contribute to acidemia. Other factors that may contribute to acidemia include diarrhea and loss of renal acidification because of impaired urea synthesis. Anorexia predisposes horses to hypokalemia.

Although infrequently reported in horses, aldosterone and water retention may cause deranged concentrations of sodium and isosthenuria (see Polydipsia, Polyuria, and the Hepatorenal Syndrome). Azotemia may occur with hyperlipemia.[65]

Cholangiohepatitis, chronic active hepatitis, or a focal hepatic abscess may cause an inflammatory leukogram, anemia of chronic disease, and hyperfibrinogenemia.[61] Primary polycythemia has been reported in horses with hepatocellular carcinoma and hepatoblastoma.[86–88] Because the liver synthesizes fibrinogen, widespread chronic hepatitis may mask an increase in this acute phase reactant protein.

14.2.4.9 Diagnostic Imaging of the Liver

Ultrasonography is a safe, noninvasive imaging technique that uses the reflection of high-frequency sound waves from tissue interfaces to produce a visual image. Ultrasonography of the liver in horses is limited by the ribs, the depth and size of the liver, and its anatomic location deep to the diaphragm and lungs. Mechanical sectoror linear array scanners with 3.0-MHz crystals are most effective.[89] One should use ultrasonography to assess the right and left sides of the liver and the liver shape, size, position, and texture. Hepatic veins are more anechoic than portal veins, and the biliary system is not normally visible. Ultrasonography of the liver is 970 most useful for determining the general size of the liver; changes in the 971 hepatic parenchyma, including abscesses, cysts, and neoplastic masses; and detecting dilated bile ducts or obstructions with choleliths. The common bile duct is not visible in a horse. Abnormal intra- or extrahepatic blood flow or vasculature may be detectable. Ultrasonography is also useful for guiding biopsy instruments into the liver (see Liver Biopsy).

Radionucleotide imaging also may be useful for detecting alterations in the hepatic parenchyma or blood flow.[90] Radionucleotide scanning noninvasively evaluates function and yields structural information. Two radionucleotide scanning techniques are available to evaluate the liver: liver scan and biliary scan. In the liver scan, one injects a technetium 99m–labeled sulfur colloid intravenously. ^{99m}Tc is a γ-emitting radioactive compound detectable in the body by a gamma camera. After injection, Kupffer's cells phagocytize the ^{99m}Tc sulfur colloid. Subsequent scanning with the gamma camera detects the radioactive emissions from the ^{99m}Tc and resolves them into a two-dimensional image. Thus alterations in blood flow (portosystemic shunt) or hepatic masses such as abscesses, cysts, and neoplasia may be detectable. In the biliary scan, one injects ^{99m}Tc-labeled iminodiacetic acid intravenously. The iminodiacetic acid is extracted by the hepatocytes, conjugated, and excreted in the bile.[91] Subsequent scanning images the biliary system and may be useful for detecting biliary obstruction including atresia, cholangitis, and cholelithiasis. Because radionucleotide imaging is expensive and requires a large gamma camera, this procedure is limited to research and academic institutions.

Operative mesenteric portography may be an option when one suspects a portosystemic shunt. In this procedure, one performs a celiotomy, injects radiopaque material into a mesenteric vein, and obtains rapid, sequential survey radiographs. Simultaneous opacification of the portal vein, azygous vein, and caudal vena cava or lack of filling of the intrahepatic portal system indicates portosystemic shunting.[90]

14.2.4.10 Liver Biopsy

A liver biopsy can yield important diagnostic, prognostic, and therapeutic information. One performs the procedure at the right twelfth to fourteenth intercostal spaces at the intersection of a line drawn from the tuber coxae to a point midway between the elbow and the point of the shoulder. One must perform the procedure in a sterile manner. The area is clipped, aseptically prepared, and injected with a local-acting anesthetic subcutaneously; then a stab incision is made with a No. 15 blade. One then inserts a Tru-Cut (Baxter-Travenol, St. Louis) or Franklin modified Vim-Silverman (Mueller & Co., Chicago) biopsy instrument and

directs it craniad and ventrad through the diaphragm into the liver. Semiautomatic biopsy instruments (EZ Core, Products Group International, Lyons, Colorado) and automatic biopsy guns (ProMag 2.2 Biopsy System, Manan Medical Products, Northbrook, Illinois) equipped with 14-gauge, 16-cm needles are helpful for a quick and accurate liver biopsy. One should place samples immediately in formalin for histopathologic evaluation and, if necessary, in transport media for culture of microorganisms. Precautions to consider before performing the procedure include the risk of hemorrhage, pneumothorax, peritonitis from bile leakage and colon or abscess puncture, and spread from infectious hepatitis. One may reduce these complications by performing a hemostasis profile to assess the risk of hemorrhage and by using ultrasonography to guide needle placement. Although subclinical coagulopathy has been reported frequently in horses with liver disease, clinically significant or fatal hemorrhage after performing a liver biopsy rarely is reported.[21,22]

14.2.4.11 Summary of Diagnostic Procedures

The most useful diagnostic tests for evaluating hepatic disease in horses are quantitation of SDH, GGT, and serum bile acids. In the face of clinically significant liver disease, at least one of the three former serum tests typically is abnormal. Although less useful in horses, additional tests of liver disease may include quantitation of bilirubin, ALP, AST, albumin, fibrinogen, globulins, glucose, esterified triglycerides, ammonia, BUN, BSP clearance, and amino acids. Serial testing of these indexes may increase their diagnostic and prognostic value. One should investigate abnormal laboratory findings further with ultrasonography and biopsy, following evaluation of a hemostasis profile.

14.2.5 TREATMENT OF HEPATIC INSUFFICIENCY

Management techniques for hepatic insufficiency are largely supportive. Therapies for specific liver diseases are discussed in more detail under Specific Hepatic Diseases. The basic goal of treatment is to maintain the animal until the liver regenerates enough to provide adequate function. Patients with severe hepatic fibrosis respond poorly because adequate regeneration often is not possible. Horses with signs of HE that are agitated, restless, or uncontrollable must be sedated to enable therapy; however, any medication should be used judiciously because most tranquilizers are metabolized by the liver or potentiate the abnormal neural function of HE. *Xylazine* or *detomidine* in small doses are safest and most effective in these instances. The use of diazepam is contraindicated because it enhances the effect of GABA on central inhibitory neurons and may exacerbate signs of HE.[32] One should correct fluid deficits and acid-base or electrolyte imbalances by administering fluids intravenously. 971
Because most horses with HE are anorectic and blood glucose may be decreased, continuous intravenous 972
infusion of *5% dextrose* at a rate of 2 ml/kg/hr can be beneficial.[92] If infusion continues more than 24 to 48 hours, substituting 2.5% to 5.0% dextrose in half-strength saline or Ringer's solution is recommended. If bicarbonate therapy is necessary to treat acidotic patients with hyperammonemia, the rate of administration should be monitored carefully because too rapid of a rate may increase blood levels of ammonia.[32] Hypokalemia or alkalosis result in increased renal production of ammonia and increased diffusion of ammonia into the CNS, thus treatment with potassium or acidifying fluids may be beneficial.[93]

The veterinarian also should direct therapy at reducing the production of toxic protein metabolites by enteric bacteria or by interfering with their absorption. The administration of *mineral oil* or magnesium sulfateper nasogastric tube is safe and aids in reducing toxin absorption. HE in human beings with acute fulminate hepatic failure almost always is associated with cerebral edema. Thus recommendations for treating severe acute HE in human beings include elective ventilation, mannitol (0.5 mg/kg body mass over 10 minutes), and continuous infusion of acetylcysteine.[94] Methods to reduce the production of ammonia and other enteric toxins include the

oral administration of antibiotics (neomycin, metronidazole, rifaximin, vancomycin) or lactulose or lactitol (not available in the United States).[93] *Neomycin* has been recommended at a rate of 10 to 100 mg/kg orally every6 hours.[57,95] This treatment significantly alters the gastrointestinal flora, may cause diarrhea in some horses, and predisposes horses to salmonellosis because most *Salmonella* species are not sensitive to neomycin. However, in one retrospective study in horses with liver disease, orally administered neomycin therapy subjectively was more helpful that lactulose in alleviating signs of HE.[22] *Lactulose*, a syrup containing lactose and other disaccharides, passes through the upper small intestine and then is metabolized by ileal and colonic bacteria to organic acids, thereby reducing luminal pH. Proposed beneficial mechanisms of action of lactulose include increased bacterial assimilation of ammonia, decreased ammonia production, ammonia trapping in the bowel lumen, enteric microflora changes, and osmotic catharsis.[24,96] A dose of 0.3 ml/kg of lactulose syrup every6 hours per nasogastric tube has been recommendedfor horses[95]; however, this therapy is expensive and may cause diarrhea. In human beings, lactulose also may be given as an enema when the oral route is unavailable.[94] When given orally 3 times a day at 333 mg/kg body mass, lactulose (Duphalac, Solvay Pharmaceuticals, Marietta, Georgia) significantly decreases blood ammonia values in healthy adult horses.[96] None of the horses developed diarrhea, though one horse foundered on the sixth day of treatment. Fecal pH did not decrease. As an alternative or adjunct to antimicrobials or lactulose, one can attempt modification of intestinal flora with probiotics such as *Lactobacillus acidophilus* or *Enterococcus faecium*.[93] Many clinicians prefer not to give antimicrobials or lactulose orally but to rely on a low-protein diet. Oral and intravenous formulations of *BCAAs* are commercially available for use in horses (BCAA Equine Sports Inc, Lake Forest, Illinois; Baxter Healthcare Corp., Deerfield, Illinois), but controlled clinical trials in human beings have not shown this therapy to ameliorate the signs of HE consistently.[39] Zinc is an important cofactor of urea cycle enzymes and may be deficient in human beings with HE. Oral supplemental with zinc is recommended in patients with zinc deficiency.[93,94]

Once the appetite returns, a horse with HE or chronic liver disease is best managed by dietary manipulation. The ration should be high in carbohydrates and low in protein, with the protein source optimally rich in BCAAs. A mixture of two parts beet pulp and one part cracked corn in molasses can be fed at a rate of2.5 kg/100 kg body mass per day divided into six or more feedings.[95] Sorghum, bran, or milo may be substituted for the beet pulp. Multiple small feedings are optimal in horses with liver disease because of impaired gluconeogenesis. Oat hay is the best roughage, followed by other types of grass hay.[92] Horses should be encouraged to graze in grass pastures, provided they are protected from the sun. Alfalfa and legumes should be avoided because of their high protein content; however, any caloric intake is important in liver failure and should be allowed even if it includes legumes. Oats, soybean meal, and fat are also not recommended.[97] One should administer vitamins B_1 and K_1 and folic acid parenterally weekly. Vitamin K therapy is most useful when cholestasis is present.[4]

A number of experimental drugs have been studiedin human beings and may have a future role in management of HE in horses. Regimens to stimulate hepatic regeneration include insulin and glucagon[98] and cytosolic extracts from regenerating liver.[99] None have been shown to be definitively effective in human beings. As discussed previously, benzodiazepine receptor antagonists have been suggested to induce clinical and electrophysiologic remissions of HE in human beings with acute and chronic liver failure.[24,100] This neuropharmacologic approach to treatment of HE holds great promise, although it may not be economically feasible in horses. In human beings with HE, treatment with *flumazenil*, a benzodiazepine antagonist, and *bromocriptine*, a dopamine agonist, have provided inconsistent results.[94]

Antiinflammatory drugs may be beneficial and include *flunixin meglumine*, dimethyl sulfoxide, and pentoxifylline. *Dimethyl sulfoxide* (0.5 to 1 gm/kg body mass given intravenously diluted to 10% for 3 to 5 days) 972

may help dissolve intrabiliary sludge or small calcium bilirubinate stones. *Pentoxifylline* has been shown to reduce hepatic fibrosis in human beings[101] and may be given to horses at 8 to 16 mg/kg every 8 to 12 hours. *Colchicine*, an antigout drug, and *cyclosporine*, a potentT helper cell immunosuppressant have been used toslow hepatic fibrosis in dogs and human beings. These drugs have not been evaluated fully in horses; however, colchicine has been ineffective in cases of pyrrolizidine alkaloid toxicity.[102]

If any drugs are to be administered to a horsewith hepatic insufficiency, altering the dosage may be necessary. Alterations in hepatic blood flow, albumin, and biotransformation during hepatic insufficiency may prolong the half-life, as well as the dosage interval. One should avoid using drugs that rely heavily on the liver for metabolism and excretion, such as chloramphenicol, erythromycin, and corticosteroids.[15]

14.2.6 PROGNOSIS

The prognosis for hepatic insufficiency in horses depends on the severity and type of the underlying disease. Horses with focal or submassive acute hepatic disease have the best chance for hepatic regeneration, thus they have a guarded to fair prognosis if adequate and appropriate supportive care is given. Patients with severe hepatic fibrosis and chronic liver disease have a poorer prognosis because of their inability to compensate for lost hepatic function. Despite the cause of liver disease, the presence of severe encephalopathy, intravascular hemolysis, profound acidosis, clinical signs of coagulopathy, diarrhea, bilateral laryngeal paralysis, greatly increased serum bile acid concentration, BSP half-life greater than 10 minutes, decreased serum albumin, and histologic evidence of bridging fibrosis have been associated independently with a poor to grave prognosis. If a horse survives more than 5 days after an acute transient hepatic insult, the prognosis is fair. Decreasing blood levels of serum bile acids and GGT are more likely to occur in horses that survive.[21] Therapy is generally unrewarding in horses with severe hepatic fibrosis.

14.3 Specific Hepatic Diseases

The variety of clinical signs with hepatic disease, coupled with the fact that the majority of the hepatic parenchyma must be affected before function is lost, makes the clinical distinction between acute and chronic liver disease a challenge. The onset of signs may be sudden, even with chronic disease. A history of progressive weight loss or failure to thrive may indicate chronicity. Although no single blood test is specific for distinguishing acute from chronic hepatic disease, the presence of hyperglobulinemia or hypoalbuminemia or both may suggest chronicity. Histopathologically, the hallmark evidence of chronicity is the presence of fibrosis. For the purpose of discussing specific hepatic disorders in the following sections, diseases have been classified as acute or chronic based on the known cause of the disease (Box 14-2).

14.3.1 ACUTE HEPATIC DISEASES

14.3.1.1 Theiler's Disease

Sir Arnold Theiler first described this disease in South Africa in 1918 following vaccination of horses against African horse sickness with live virus and equine-origin antiserum.[103] In 1934 and 1937, a similar disease was described in the United States following vaccination of horses against western equine encephalomyelitis using live virus and equine-origin antiserum.[58,104,105] Despite numerous accounts of this syndrome, the exact cause of Theiler's disease remains unclear. Today this disease is one of the most commonly described causes of

acute hepatic failure in horses.[19,58,106–108] Theiler's disease also is referred to as *acute hepatic necrosis, serum-associated hepatitis*, and *serum sickness*.

14.3.1.1.1

Clinical Signs

Theiler's disease is limited to adult horses, though one report describes subclinical disease in a2-month-old foal.[107] The onset of clinical signs of hepatic failure in Theiler's disease is acute to subacute and often rapidly progresses over 2 to 7 days. Most horses are anorectic and icteric; HE is reported in most cases. Sudden death, photodermatitis, hemorrhagic diathesis, fever, dependent edema, colic, and bilirubinuria may be present.[58,106,107] Although uncommon, some horses with Theiler's disease have an insidious history of chronic weight loss.

14.3.1.1.2

Epidemiology and Pathogenesis

The disease typically occurs sporadically, but outbreaks involving multiple horses on a single farm over several months have been reported. A pattern of seasonality may occur, with a larger percentage of cases presenting in summer and fall.[58,106,107] Frequently, horses with Theiler's disease have received an equine-origin biologic 4 to 10 weeks before the onsetof hepatic failure, hence the name *serum-associated hepatitis*. Equine-origin biologics that have been associated with Theiler's disease include vaccines or antisera for African horse sickness, eastern and western encephalomyelitis, *Bacillus anthracis*, tetanus antitoxin, *Clostridium perfringens, C. botulinum, Streptococcus equi,* influenza, equine herpesvirus type 1, and pregnant mare's serum.[16,58,106,107] Some reports suggest that lactating broodmares given tetanus antitoxin after parturition are particularly prone to Theiler's disease.[106–108]

Reports of outbreaks associated with parenteral injection of homologous live virus vaccine or antiserum suggest an infectious blood-borne viral cause.[58] The history, onset, clinical signs, and histopathologic 973
findings of Theiler's disease appear most similar to hepatitis B virus in human beings. Hepatitis B virus is 974
present in all body fluids and excreta and is transmitted primarily by parenteral injection.[109] Viral surface antigen or antibody to viral core protein is detectable in 75% to 90% of human patients with hepatitis B.[77] Newer techniques that detect viral DNA or DNA polymerase are even more sensitive and specific tests of infection. To date, these assays have been negative in horses with Theiler's disease. Furthermore, viral isolation on horses with Theiler's disease has been unsuccessful, the disease has not been transmitted experimentally by blood or tissue inoculation, and a large percentage of horses with Theiler's disease do not have a recent history of receiving an equine-origin biologic.[110,111] The sum of these negative findings does not necessarily exclude the possibility of a viral cause. However, ifsuch exists, other modes of transmission, infection, and establishment of disease must exist.

14.3.1.1.2.1

BOX 14-2 LIVER DISEASES OF HORSES

14.3.1.1.2.1.1

Acute Disease

Theiler's disease (serum-associated hepatitis)

Hyperlipemia

Tyzzer's disease

Infectious necrotic hepatitis (black disease)

Cholangiohepatitis

Acute biliary obstruction

- Cholelithiasis
- Colon displacement
- Hepatic torsion

Parasitic hepatitis

- *Parascaris equorum*
- Large strongyles
- *Echinococcus granulosus*
- *Schistosoma*

Toxic hepatopathy

- Plants
- Mycotoxins
- Chemicals
- Drugs
- Iron

Viral hepatitis

- Equine infectious anemia
- Equine herpes virus 1
- Equine viral arteritis
- Giant cell hepatopathy

14.3.1.1.2.1.2

Chronic Disease

Pyrrolizidine alkaloid toxicity

Clover poisoning

Chronic active hepatitis

Cholelithiasis

Gastroduodenal obstruction

Abscess

Neoplasia

- Metastatic infiltration of the liver
- Cholangiocarcinoma
- Hepatocellular carcinoma
- Hepatoblastoma
- Mixed hamartoma

Amyloidosis

Chronic hypoxia

14.3.1.1.2.1.3 Congenital or Heritable

Portosystemic shunt

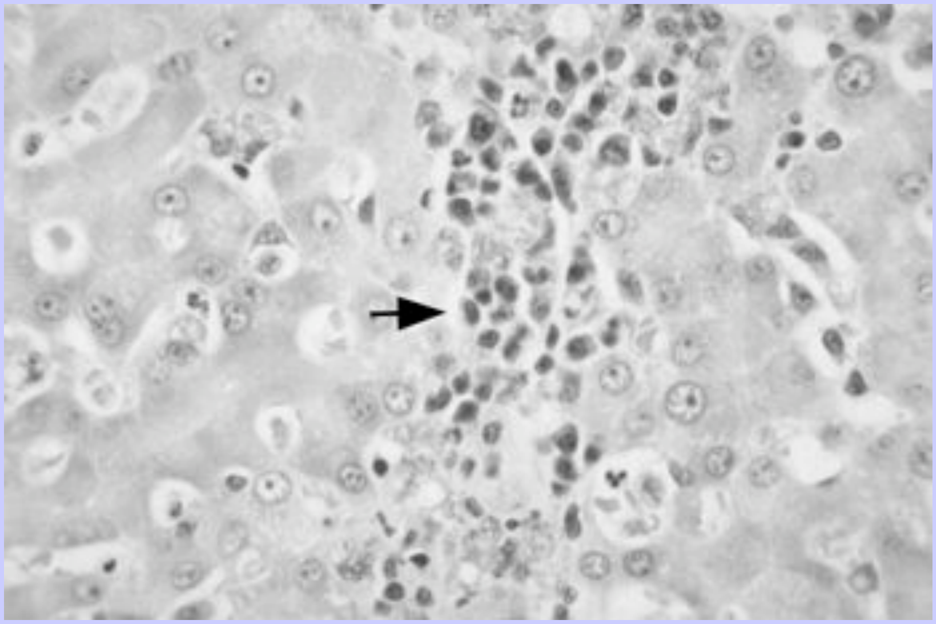
Biliary atresia

Hyperammonemia of Morgans

Other suggested causes of Theiler's disease include exposure to hepatotoxic substances, such as mycotoxins (aflatoxin and rubratoxin), plant toxins (pyrrolizidine alkaloids, alsike clover), drugs, or chemicals.[16,108] However, these causes have not been uniformly demonstrable and usually are considered separate disease entities.

Aside from widespread tissue icterus, the pathologic findings are limited to the liver. The liver appears smaller than normal but may be large in peracute cases. Although not pathognomonic, the histopathologic findings in Theiler's disease consistently include widespread centrilobular to midzonal hepatocellular necrosis with hemorrhage (Figure 14-7),[110] which helps distinguish it from acute pyrrolizidine alkaloid toxicity, which has predominantly periportal changes. Moderate to severe centrilobular hepatocyte vacuolar (fatty) change and granular swelling, hemosiderosis, and bile casts may be evident.[106] A mild inflammatory infiltrate, primarily monocytes and lymphocytes, is present in the portal triads. The occasional finding of 974
mild to moderate biliary hyperplasia and fibroblastic infiltration is evidence of a more chronic disease 975
course than the clinical signs alone suggest.[110]

Figure 14-7 Histopathology of the liver: Theiler's disease. The central area shows hepatic necrosis *(arrow)*.



14.3.1.1.3
Diagnosis

Recent inoculation with an equine-origin biologic, coupled with an abrupt onset of clinical signs and laboratory evidence of hepatic insufficiency, strongly suggests Theiler's disease. No single laboratory test is diagnostic. Bilirubinemia and bilirubinuria are usually present. Liver enzymes, including SDH, arginase, and AST, are increased. The BSP half-life, PT, and APTT often are prolonged, and blood ammonia concentrations are increased. Acidosis, leukocytosis, polycythemia, and increased serum creatine kinase activity also have been reported.[106–108] Hemolysis may occur terminally. The histopathologic findings on a liver biopsy (see preceding Epidemiology and Pathogenesis section) offer the strongest diagnostic evidence of Theiler's disease.

14.3.1.1.4
Treatment

No specific treatment for Theiler's disease exists aside from general supportive care for hepatic insufficiency (see Treatment of Hepatic Insufficiency).

14.3.1.1.5
Prognosis and Client Education

The prognosis is poor to grave in horses with severe HE, hemorrhage, or hemolysis. Horses that survive longer than a week usually recover completely, though death or progressive weight loss have been reported during the ensuing months.[107] A favorable prognosis is warranted if serial SDH activities are decreasing or clinical signs are waning. Increased serum activity of GGT may be sustained for several weeks, despite

clinical improvement and long-term survival.[106] No preventative exists, aside from the judicious use of equine-origin antiserum.

14.3.1.2

Bacterial Hepatitis

14.3.1.2.1

Tyzzer's Disease

Clostridium piliformis (formerly, *Bacillus piliformis*) is a motile, spore-forming, obligate intracytoplasmic bacterium that causes acute necrotizing hepatitis. The disease was first described by E.E. Tyzzer in 1917 in a colony of waltzing mice.[112] The first documented outbreak in foals occurred in Kentucky on a single farm between 1964 and 1973, fatally infecting23 foals.[113]

14.3.1.2.2

Clinical Signs

In horses, Tyzzer's disease is limited to foals between the ages of 7 and 42 days.[114–116] The clinical signs are usually nonspecific and include loss ofa suckle reflex, depression progressing to recumbency, fever, tachypnea, tachycardia, icterus, petechiation, diarrhea, dehydration, shock, seizures, and coma.[113–118] Often the foals are found dead without premonitory signs.

14.3.1.2.3

Epidemiology and Pathogenesis

Outbreaks of Tyzzer's disease are sporadic, thus the disease is not believed to be contagious.[116] Seasonality has not been demonstrated. The disease has been reported in the United States, Canada, South Africa, England, and Australia.[116,117] Mice with Tyzzer's disease are infected by an oral route perinatally, with clinical signs and death occurring between 6 and 44 days of age.[117] *C. piliformis* is excreted in the feces of clinically healthy horses and can survive in the soil for at least 1 year.[115,117] Foals are infected by eating contaminated feces of their dams or by ingesting contaminated soil. The bacteria replicate in the intestinal epithelium and reach the liver and heart by way ofthe lymphatics and blood supply.[115] In rodents and rabbits, administration of corticosteroids or sulfonamides may induce active disease.[117] The presence of antibody to the flagella of *C. piliformis* in the serum of healthy horses suggests that *exposure* to *C. piliformis* is not uncommon.[119]

C. piliformis causes acute multifocal hepatitis and enteritis. Grossly, the liver is swollen with 1- to 5-mm white foci scattered throughout the parenchyma. Tissues are icteric, and petechial hemorrhages are presentin many tissues. Microscopically, the foci are areas of coagulative necrosis with an associated inflammatory infiltrate consisting of neutrophils, macrophages, and lymphocytes. The organisms, best demonstrated atthe periphery of the lesions by Warthin-Starry or Dieterle's silver stains, appear as long bacilli organizedin bundles. In addition to hepatitis, enterocolitis, myositis, pleural effusion, pulmonary congestion and edema, and lymphoid necrosis or depletion may be present.[116,117]

14.3.1.2.4

Diagnosis

The peracute onset and nonspecific signs confound antemortem diagnosis of Tyzzer's disease. Hematologic study may reveal hemoconcentration, leukopenia or leukocytosis, a left shift, and toxic neutrophils.[114–117]

Other nonspecific laboratory findings include hyperfibrinogenemia, acidosis, hyperkalemiaor hypokalemia, and profound hypoglycemia. Liver enzymes are increased, including SDH, GGT, AST, ALP, and LDH-5.[114–118]

One makes the definitive diagnosis at necropsy by demonstrating the organism intracytoplasmically using silver stains. *C. piliformis* is fastidious and can be grown only in living tissue, such as embryonated chick eggs.[118] Positive serologic tests may support evidence of exposure.[119] Differential diagnosis for hepatic diseasein foals includes iron hepatotoxicity, perinatal equine herpesvirus type 1, bacteremia, atresia of the bile duct, and portosystemic shunt.

14.3.1.2.5 Treatment

Tyzzer's disease is highly fatal in foals. In rodents and rabbits, *C. piliformis* is sensitive to penicillin, tetracycline, erythromycin, and streptomycin. A report describes successful treatment of a foal with presumed Tyzzer's disease using penicillin, trimethoprim-sulfonamide (TMS), and partial parential nutrition.[114]

14.3.1.2.6 Prognosis and Client Education

Tyzzer's disease in foals is considered highly fatal. No preventative exists. 975

976

14.3.1.3 Infectious Necrotic Hepatitis

Clostridium novyi type B is the cause of *infectious necrotic hepatitis* or *black disease*. The disease is most common in sheep and cattle, but several cases have been documented in horses.[56,120–123]

14.3.1.3.1 Clinical Signs

The onset of disease may be peracute with sudden death. Acute signs progress over 24 to 72 hours and include depression, reluctance to move, fever, icterus, ataxia, colic, petechiae, periods of recumbency, tachycardia, and tachypnea.[56,120–123] Some affected horses remain standing until a short time before death.

14.3.1.3.2 Epidemiology and Pathogenesis

Reported cases of infectious necrotic hepatitis in horses have occurredin or adjacent to areas with a large population of sheep.[56,120–123] In sheep and cattle, infectious necrotic hepatitis results from multiplication of *C. novyi* in areas of liver compromised by the migration of *Fasciola hepatica*. This fluke normally does not infest horses, but migration of any parasite through the liver may predispose the horse to infectious necrotic hepatitis. Some horses with infectious necrotic hepatitis had parasitic infestations, though migration of parasites in the liver at the timeof necropsy was not evident. The onset of disease inone case occurred 48 hours after administration of mebendazole.[56]

The carcass blackens rapidly after death because of engorgement of subcutaneous blood vessels; hence the name *black disease*. Often, necropsy findings include serosanguineous effusion in the pericardial sac, the thoracic and abdominal cavities, widespread hemorrhages and icterus, and multifocal areas (1 to 2 mm) of

coagulative hepatic necrosis. Smears or histologic sectionsof the hepatic lesions reveal large numbers of gram-positive rods.

14.3.1.3.3 Diagnosis

The acute and nonspecific nature of this disease makes antemortem diagnosis improbable. Liver-specific enzymes and bilrubin were mildly to moderately increased.[56,120,123] An abdominocentesis was performed on one horse that revealed serosanguineous peritonitis.[56] Definitive diagnosis is based on positive staining with fluorescein conjugated antiserum specific for *C. novyi*, or isolation of the organism at necropsy.[120,123] The organism is difficult to isolate and requires rapid tissue sampling and anaerobic conditions.

14.3.1.3.4 Treatment

Treatment with high doses of penicillin or ampicillin are indicated, in addition to general supportive care for hepatic insufficiency.

14.3.1.3.5 Prognosis and Client Education

Most reported cases of infectious necrotic hepatitis in horses were fatal.

14.3.1.4 Miscellaneous Causes of Bacterial Hepatitis

Primary bacterial hepatitis is rare in adult horses. Bacterial septicemia in neonates may result in multifocal hepatitis, though the disease rarely is accompanied by clinical signs of hepatic failure. Bacterial endotoxin, released during acute fulminant gram-negative infection or absorbedfrom the gastrointestinal tract following mural damage, may cause hepatic ischemia indirectly through hemodynamic alternations. Because Kupffer's cells normally phagocytose endotoxin, bombardment of the liver with endotoxin temporarily may impede the function ofKupffer's cells.

Primary bacterial cholangiohepatitis has been reported in horses, though more commonly it is secondary.[51,124–127] *Secondary cholangiohepatitis* in horses is a sequela to biliary stasis, cholelithiasis, chronic active hepatitis, hepatic neoplasia, pancreatitis, enterocolitis, intestinal parasitism, and intestinal obstruction. Clinical signs include anorexia, colic, fever, and icterus. HE may be present. Laboratory abnormalities may include leukocytosis; toxemia; hyperfibrinogenemia; increased activity of SDH, arginase, GGT, and direct reacting bilirubin; and septic or nonseptic peritonitis.[125,127] Definitive diagnosis is based on histopathologic findings on liver biopsy and bacterial isolation. Isolates are most commonly enteric organisms such as *Salmonella* species, *Escherichia coli*, and *Citrobacter, Klebsiella, Aeromonas*, and *Acinetobacter* species.[125–127] Treatment includes general supportive care for hepatic failure (see Treatment of Hepatic Insufficiency) and 4 to 6 weeks of antimicrobial therapy. One should base the antimicrobial therapy on culture and sensitivity results. Recommended antimicrobials for bacterial cholangiohepatitis in horses include trimethoprim-sulfonamide, ceftiofur, enrofloxacin, penicillin and gentamicin, ampicillin, and chloramphenicol.[51,124–127]

14.3.1.5 Viral Hepatitis

14.3.1.5.1 Equine Herpesvirus Infection in Foals

Pregnant mares infected with equine herpesvirus type 1 may abort in the third trimester or deliver stillborn or weak foals. Some foals may appear normal at birth but develop clinical signs of respiratory distress, icterus, fever, and severe depression.[128,129] Secondary bacterial septicemia is common. Despite profound hepatic necrosis in herpesvirus-positive foals, serum enzyme activities were not significantly different from premature foals or foals with septicemia.[129] Pathologic lesions of aborted fetuses or neonatal foals are similar and include severe pulmonary congestion, pneumonitis, bronchiolitis, hyaline membrane disease, and intralobular coagulative hepatocellular necrosis.[128,129] Intranuclear, acidophilic inclusions are present in hepatocytes and biliary epithelium. No specific treatment exists for equine herpesvirus infection. General supportive care and prophylactic administration of broad-spectrum antimicrobials are indicated. The prognosis is poor to grave. Most affected foals die within a few days of birth. Vaccination of pregnant mares is only partially efficacious for prevention. 976

977

14.3.1.5.2 Equine Infectious Anemia

The causative organism of equine infectious anemia is a retrovirus that has a tropism for mononuclear phagocytes.[130] Although cyclic fever, anemia, icterus, edema, and weight loss are the systemic manifestations of the disease, the Kupffer's cells in the liver are a major site of infection. Icterus is caused by increased erythrocyte destruction and by acute hepatic necrosis.

14.3.1.5.3 Equine Viral Arteritis

Equine viral arteritis is caused bya togavirus and typically is manifested clinically by depression, fever, acute upper respiratory tract infection, abortion, petechiation, and edema. Following ingestion or inhalation, viral septicemia leads to vascular damage. Overt clinical signs of hepatic disease are rare, but vascular damage in the liver may cause icterus.[131]

14.3.1.5.4 Giant Cell Hepatopathy

A disease similar to human neonatal hepatitis has been reported in aborted midterm fetuses. Histologically, disorganization of hepatic cords, multifocal necrosis, a mild mononuclear cell infiltrate, and a large hepatocyte syncytium with 8 to 10 nuclei are evident. The cause in horses and human beings is unknown but is presumably viral. Viral and bacterial isolation, viral immunofluorescence, and serologic testing have been unsuccessful in horses. Giant cell hepatopathy was reported in one foal with prolonged neonatal isoerythrolysis.[132]

14.3.1.6 Parasitic Hepatitis

Parasitic infestation may cause focal hepatic disease but rarely overt hepatic insufficiency. Following their ingestion as embryonated eggs, larvae of *Parascaris equorum* hatch in the small intestine and then migrate through the liver and lungs. Focal or diffuse hepatic fibrosis may result. Migration of *Strongylus edentatus* or

S. equinus through the hepatic portal veins may cause focal hepatitis, subcapsular hemorrhage, and edema followed by focal parenchymal fibrosis and capsular fibrin deposits.[133] Focal hepatic infarcts may occur following thrombotic emboli caused by migrating *S. vulgaris* in mesenteric arteries. Protozoal schizonts consistent with a *Sarcocystis* species other than *Sarcocystis neurona* were reported at necropsy in the liver of a horse with concurrent bacterial osteomyelitis, a plasma cell tumor of the maxilla, and hepatic salmonellosis.[134] The canine cestode *Echinococcus granulosus* may form hydatid (larval) cysts in the liver, which are usually an incidental finding.[135,136]

Fibrosing granulomata were found in the liver, intestinal and diaphragmatic serosae, and lung of several horses submitted for necropsy.[137] The granulomata consisted of dense fibrous tissue surrounding a necrotic, laminated, mineralized center. The periphery of the granuloma contained a small rim of inflammatory cells. The typical architecture of the granulomata, combined with the finding of a residual egg shell typical of *Schistosoma* (a trematode) in one horse, led to the conclusion that the granulomata were caused by chronic schistosomiasis. Although the granulomata were considered to be incidental findings of undetermined origin in most ofthe horses, they caused liver failure in one horse.

14.3.1.7

Toxic Hepatopathy

Numerous chemicals, drugs, mycotoxins, and plant toxins are hepatotoxic, but these rarely cause acute hepatic failure in horses. Clinical signs and routine laboratory diagnostics do not distinguish between these toxins, thus diagnosis largely relies on exclusion of other causes, history of exposure, and in some cases documentationof the toxin in the blood or liver. Some substances cause fatty change, cloudy swelling, necrosis, mild inflammatory infiltration, and fibrosis, primarily in the centrilobular location where the oxygen tension is lowest. Other substances cause the same lesions periportally in thearea of initial exposure. Some substances are directly hepatotoxic; others require biotransformation by the liver to toxic metabolites.

14.3.1.7.1

Hepatotoxic Plants

Plants best known for causing hepatic disease in horses are those containing pyrrolizidine alkaloids. Although pyrrolizidine alkaloid toxicity can cause acute hepatic necrosis, it more often results in hepatic fibrosis and is discussed as a separate entity under Chronic Hepatic Diseases. Other plants that have been reported to cause hepatic necrosis in horses in North America include kleingrass *(Panicum coloratum)*, *Lantana*, lecheguilla *(Agave lecheguilla)*, whitebrush (*Lippia* spp.), sneezeweed (*Helenium* spp.), blue-green algae (*Microcystis* and *Nodularia* spp.), lupine (*Lupinus* spp.), ryegrass, and some poisonous mushrooms (*Amanita* and *Galerina* spp.).[102]

14.3.1.7.2

Chemical Hepatotoxins

Horses rarely are exposed to hepatotoxic chemicals in sufficient amounts to induce hepatic failure. Potential hepatotoxic chemicals include arsenic (pesticide), carbon tetrachloride (fumigant), chlorinated hydrocarbons (insecticide), carbon disulfide (botacide), monensin (ionophore), pentachlorophenols (wood preservative, herbicide, fungicide), phenol (disinfectant, wood preservative), phosphorus (fertilizer), polybrominated biphenyl (fire retardant), and paraquat (herbicide).[138] All of these cause centrilobular necrosis, except phosphorus, which causes primarily periportal changes.

14.3.1.7.3

Drugs

Pharmaceutical agents can have wide range of effects on the liver depending on the drug type, dose, frequency, duration, route of administration, age of the animal, diet, and concurrent treatment.[139] The hepatic damage may be acute or chronic, cholestatic, zonal, vascular, or hypersensitivity-mediated. Certain drugs alter hepatocellular permeability without visible injury or loss of function. 977

978

Drugs that are intrinsically hepatotoxic reproducibly cause hepatocellular necrosis.[138,140] Examples of intrinsic hepatotoxic drugs that cause zonal centrilobular necrosis include carbon disulfide and carbon tetrachloride.[138] Hepatocellular damage caused by these drugs is dose-related, and toxicity often results in hepatic failure. Anabolic steroids cause cholestasis with little or no evidence of hepatic damage or inflammation, resulting in mild icterus, which is completely and rapidly reversible once the drug is discontinued.[139,140] Phenothiazines and macrolide antibiotics (erythromycin) cause cholestatic injury, which is accompanied by significant hepatocellular necrosis and periportal inflammation.[140] Recovery usually is expected after discontinuation of the drug. Some drugs, such as tetracycline, cause fatty infiltration of the liver but rarely cause liver dysfunction.

Idiosyncratic hepatotoxicity has been reported following administration of erythromycin, rifampin, tetracycline, isoniazid, halothane, fluothane, phenothiazines, dantrolene, diazepam, sulfonamides, phenobarbital, phenytoin, and aspirin.[102,138,140] Injury varies from mild focal hepatitis to massive necrosis. Idiosyncratic hepatopathy has a low incidence, is not dose related, and often resolves on discontinuation of the drug. Rarely, progressive liver failure ensues. Some idiosyncratic drug hepatopathies may have a pathogenesis similar to drug allergy. Others may be related to the biotransformation properties of the liver. For example, if an individual has enhanced biotransformation of a certain drug and the metabolite of the drug is more cytotoxic than the original unaltered drug, hepatic damage may ensue.

Finally, some drugs induce increased hepatic enzyme activities or alter hepatocellular permeability but do not cause significant hepatic damage or clinical signs. Examples include benzimidazole anthelmintics, phenobarbital, phenylbutazone, and corticosteroids. Compared with human beings and dogs, corticosteroids are apparently less likely to cause hepatopathy in horses; however, a report describes steroid hepatopathy in a horse that received an overdose of triamcinolone for treatment of pruritus.[141] Three weeks after the overdose, the horse developed muscle wasting, depression, polydipsia, and laminitis. Mature neutrophilia, lymphopenia, hyperglycemia, increased serum activities of AST and GGT, and multizonal hepatocellular vacuolation were reported.

14.3.1.7.4

Iron Toxicity

Acute, fatal toxic hepatopathy was reported in numerous newborn foals given an oral microbial inoculum.[52] The syndrome is reproducible if one gives *ferrous fumarate* orally. The incidence of hepatic failure was highest when the foals were given the inoculum before nursing. Colostrum contains abundant vitamin E, an essential cofactor for glutathione. Glutathione protects against free radical damage, a proposed mechanism for iron toxicity. Thus, presumably, foals that are given iron supplements before ingesting colostrum are most susceptible to iron toxicity.[142]

Clinical signs include HE, icterus, and peracute death. Laboratory abnormalities include increased blood levels of bilirubin, SDH, GGT, and ammonia, and reduced BCAA:AAA ratio, decreased glucose, and prolonged PT. At necropsy the liver was abnormally small, and histologic study revealed massive hepatic necrosis with blood-filled reticula. Some livers had mild biliary hyperplasia and periportal fibrosis. Supportive therapy may prolong life, but most foals with iron hepatotoxicosis die. Those foals that survived recovered fully.

Adult horses are less susceptible to iron toxicitiy; however, rare cases of hemochromatosis have been reported.[143,144] Hemochromatosis is characterized by tissue damage and dysfunction caused by deposition of hemosiderin in parenchymal cells. Hemochromatosis was diagnosed in three adult horses by histopathologic examination and use of Prussian blue stain, which detects iron deposition (hemosiderin pigment).[143] Excessive dietary iron was not apparent. All three of the horses had signs and laboratory evidence of liver disease. Serum iron concentration was normal, with no evidence of saturation of the iron transport system in the serum. Hemochromatosis was accompanied by bile duct hyperplasia and hepatic fibrosis. All three horses died or were euthanized because of deterioration. Hemochromatosis was diagnosed in a pony receiving approximately 4 times the daily recommended amount of iron.[144] The diagnosis was confirmed by histopathologic examination (severe periportal fibrosis, hemosiderosis, biliary hyperplasia) and increased serum and liver concentrations of iron.

14.3.1.7.5 Mycotoxins

Mycotoxicosis is more common in ruminants than in horses. The two most common mycotoxins affecting horses are *aflatoxin*, produced by the molds *Aspergillus flavus* and *A. parasiticus*, and *rubratoxin*, produced by the mold *Penicillium rubrum. Aspergillus* species grow on a variety of feedstuffs if the temperature, moisture, and carbohydrate content are sufficient.[138] Aflatoxins impair protein synthesis and carbohydrate metabolism.

The degree of hepatic damage and extent of clinical signs depend on the duration and extent of exposure to the mycotoxin. Most horses refuse to eat moldy feed, thus hepatic failure is uncommon. Pathologic findings include hepatocellular necrosis, fatty change, biliary hyperplasia, periportal fibrosis, and megalocytosis. No specific treatment exists for aflatoxicosis. Administration of activated charcoal or a cathartic shortly after ingestion may impede absorption. Mycotoxicosis is best prevented by avoiding moldy feed.

Fumonisin B1, the mycotoxin of *Fusarium moniliforme*, most frequently is associated with contaminated 978
corn and causes leukoencephalomalacia in horses. The mycotoxin also causes hepatocellular necrosis and 979
periportal fibrosis. Although most horses with leukoencephalomalacia have hepatic disease, signs of leukoencephalopathy predominate and hepatic failure is rare. Recovery from hepatic disease is more likely than from the neurologic disease.

14.3.1.8 Acute Biliary Obstruction

Acute obstruction of the common bile duct causes icterus and signs of abdominal pain. Acute biliary occlusion may occur following cholelithiasis (see Cholelithiasis) or colon displacement. Intense icterus, colic, and increased levels of direct bilirubin (>85.5 μmol/L), GGT (>400 units/L), and bile acids (>150 units/L) were reported in two horses with acute colon displacements.[82] These abnormalities quickly abated after surgical correction of the displaced colon. Torsion of the left lobe of the liver was the cause of acute colic, hepatic

congestion, necrosis, and focal hepatitis in a 14-year-old Arabian gelding.[145] Resection of the affected lobe resulted in complete recovery.

14.3.1.9 Hyperlipemia and Hepatic Lipidosis

Hyperlipemia occurs primarily in ponies and Miniature horses and donkeys and may lead to fatty infiltration of the liver, often accompanied by clinical signs of liver disease and a poor prognosis. *Hyperlipidemia* refers the conditions causing an increase in serum trigylceride concentration (generally less than 500 mg/dl) without grossly lactescent blood or fatty infiltration of the liver. Obesity, stress, inability to satisfy metabolic energy demands, and hormonal imbalance are the major precipitating factors for hyperlipemia.[146–151]

14.3.1.9.1 Epidemiology and Clinical Signs

Ponies, especially Shetland ponies and mare ponies, and Miniature horses and donkeys are most susceptible to hyperlipemia. Rarely, other breeds such as the Quarter Horse, Paso Fino, and Tennessee Walking Horse may be affected. Affected ponies are usually obese, have a recent history of stress or weight loss, and are in late gestation or early lactation during the winter months.[60] In Miniature horses and donkeys, hyperlipemia can occur at any age and frequently develops as a sequela to an underlying primary illness of several days' duration. The most commonly reported primary diseases predisposing Miniature horses to hyperlipemia are enterocolitis, endotoxemia, parasitism, pituitary adenoma, azotemia, and neonatal septicemia.[150,151] The onset of clinical signs of hyperlipemia is often acute and includes icterus, anorexia, weakness, severe depression, ataxia, muscular weakness, recumbency, diarrhea, mild colic, fever, and dependent edema.[60,146,148] In severe cases, clinical signs of hepatic failure may prevail (see Clinical Signs of Hepatic Insufficiency). Sudden death caused by hepatic rupture may occur.[147] Signs of predisposing primary disease in Miniature horses may overshadow signs of hyperlipemia.

14.3.1.9.2 Pathogenesis

The liver serves a unique role in energy homeostasis (see Physiology), especially in large animals in which volatile fatty acids, and not glucose, are a major energy source. Glucose is manufactured primarily in the liver from fatty acids and amino acids and is stored as glycogen for future use. If intake is decreased or energy demands are increased, glycogen stores become depleted, and the major source of energy is provided by fatty acid oxidation. Obesity sets the stage for hyperlipemia by providing excessive adipose tissue stores of fatty acids, available for immediate and rapid mobilization. Fatty acid mobilization is usually first triggered by a stress or inability to maintain energy homeostasis. Concurrentor underlying primary diseases—such as enterocolitis, azotemia, infection, parasitism, or neoplasia or any stressful event such as transport or weaning—may precipitate fatty acid mobilization. Stress increases the release of catecholamines and glucocorticoids, which stimulate fatty acid release from the adipose tissue. A negative energy balance, as may occur during late gestation, early lactation, starvation, or following anorexia induced by some other primary disease, exacerbates hyperlipemia by further promoting fatty acid mobilization.

After lipolysis of adipose tissue triglyceride occurs, free fatty acids, nonesterified fatty acids, and glycerolare released into the blood. Glyceride, fatty acids boundto albumin, and nonesterified fatty acids are carried to the liver, where the glyceride is converted to glucose (see Figure 14-3). In the liver, free fatty acids may be oxidized to acetyl coenzyme A and used in the tricarboxylic acid cycle; used in gluconeogenesis; resynthesized to triglycerides and stored in the liver; or used to make triglycerides that are

released into the sinusoidal blood as VLDLs. Ponies with hyperlipemia have larger diameter VLDLs containing greater concentrations of triglycerides than normal ponies. Thus hyperlipemia in ponies and Miniature horses results from efficient hepatic synthesis of triglycerides from mobilized free fatty acids, with subsequent secretion of triglyceride laden VLDLs into the blood. Endothelial lipoprotein lipase is the rate-limiting enzyme responsible for the removal of VLDLs from the blood back into adipose tissue. In hyperlipemic ponies, the activity of lipoprotein lipase is not impaired and in fact is increased several times. Thus the overproduction of VLDLs by the liver and not impairment of their removal is primarily responsible for hyperlipidemia in ponies.[152,153]

If the oxaloacetate supply is limited when free fatty acids are mobilized to the liver, acetyl coenzyme A is
shuttled away from the tricarboxylic acid cycle and used to make ketone bodies. Because the equine liver is 979
efficient in synthesizing triglycerides and exporting VLDLs, hepatic lipidosis and ketosis are less common 980
than in other species.[149] However, if fatty acid mobilization and synthesis of triglycerides exceed oxidation and VLDL secretion, hepatic lipidosis ensues. Fat infiltration disrupts hepatic function, and excessive amounts of fat in the liver can result in hepatic failure and even hepatic rupture.[147]

Hormonal factors may contribute to the development of hyperlipemia and hepatic lipidosis. Insulin normally impedes the development of hyperlipemia by inhibiting tissue hormone–sensitive lipase, the enzyme responsible for lipolysis of adipose tissue. Insulin also curtails the development of hyperlipemia by stimulating gluconeogenesis in the liver and by activating lipoprotein lipase, the enzyme responsible for uptake of VLDL by adipose tissue. Despite often normal insulin levels, ponies appear to have a tissue insulin insensitivity compared with horses.[147] Fasting in donkeys has been shown to cause a reduction in tissue sensitivity to insulin.[154] Glucocorticoids, catecholamines, adrenocorticotropic hormone, thyroid-stimulating hormone, growth hormone, antidiuretic hormone, and progesterone may contribute to the development of hyperlipemia by opposing the biologic actions of insulin (see Figure 14-3). This may accountfor the high incidence of hyperlipemia during periods of increased cortisol levels (stress, pituitary adenoma, late pregnancy) and increased progesterone (pregnancy). In ponies, norepinephrine linearly stimulates the release of free fatty acids from adipose tissue, an effect which does not occur in horses.[155] Considering the unique effects of insulin and catecholamines on fat metabolism in ponies, not surprisingly ponies are more susceptible than horses to develop hyperlipemia.

Vascular thrombosis can occur following hyperlipemia and fat embolism and may be evident in the lung, kidney, brain, and subcutaneous vessels. Subcutaneous thrombosis causes dependent edema. Renal nephrosis and necrotizing pancreatitis are sometimes present.[60,147] Renal disease most likely is a sequela of occlusive thrombosis. The exact cause of pancreatitis is not known; however, hyperlipemia precedes pancreatitis. Excessive lipid is speculated to be deposited in and around the pancreas, which is hydrolyzed subsequently by pancreatic lipase, and released as free fatty acids. Free (unbound to albumin) fatty acids are cytotoxic, and when the albumin binding capacity is exceeded, pancreatic vascular injury occurs.[156]

Azotemia prevents lipid removal from the blood by inhibiting lipoprotein lipase. The degree of hyperlipidemia correlates directly with the degree of azotemia.[157] Almost half of hyperlipemic Miniature horses are azotemic.[150,151] Compared with ponies and Miniature horses, hyperlipemia rarely develops in horses, though *hyperlipidemia* (trigylcerides <500 mg/dl) may develop during azotemia.[148,157] Mild hepatic lipidosis may ensue, but hyperlipidemia rarely results in clinically recognizable disease.

14.3.1.9.3

Diagnosis

One should consider hyperlipemia in the differential diagnosis for any obese pony or Miniature horse with clinical signs of severe depression, anorexia, ataxia, and icterus. The normal triglyceride level in horses and ponies should be less than 85 mg/dl but may be up to 290 mg/dl in healthy donkeys and up to 250 mg/dl in healthy pregnant pony mares.[153] In hyperlipemia, the blood grossly appears opalescent (Figure 14-8) and the concentrations of all lipids are increased, especially triglycerides (>500 mg/dl), nonesterified fatty acids, and VLDLs. Laboratory evidence of hepatic disease may include increased serum activity of SDH, GGT, increased concentrations of serum bile acids, bilirubin, and ammonia, and decreased glucose, BUN, and albumin.[146] In hyperlipemic Miniature horses, only about half of affected patients have significant hepatic impairment.[150] The BSP half-life is prolonged. Oral and intravenous glucose challenge tests may reveal glucose intolerance because of insulin insensitivity. Metabolic acidosis is frequent, and one should suspect ketoacidosis if the anion gap is increased. Lipemia may increase serum creatinine values falsely and interfere with accurate determination of other serum chemistries. One confirms a diagnosisof hepatic lipidosis by the concurrent demonstration of increased blood concentrations of lipid, laboratory evidence of 980 hepatic dysfunction, and ultrasonographic or histopathologic findings of fatty infiltration in the liver (Figure 981 14-9). One should determine the serum concentrations of creatinine and electrolytes as an adjunctto therapy. Because of the incidence of hyperlipemiain ill Miniature horses and donkeys, monitoring blood triglyceride levels facilitates early recognition of hyperlipidemia in these patients.

Figure 14-8 Hyperlipemia. The spin hematocrit tube on the right is from a Miniature horse with hyperlipemia. The hematocrit tube on the left is from an unaffected horse.

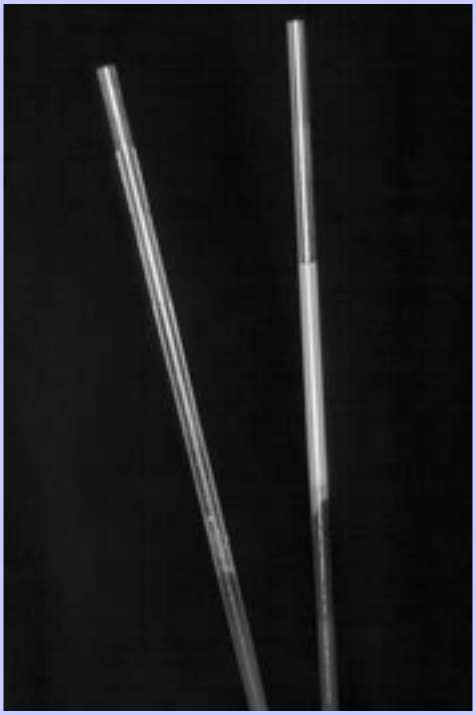


Figure 14-9 Histopathology of the liver: fatty liver.

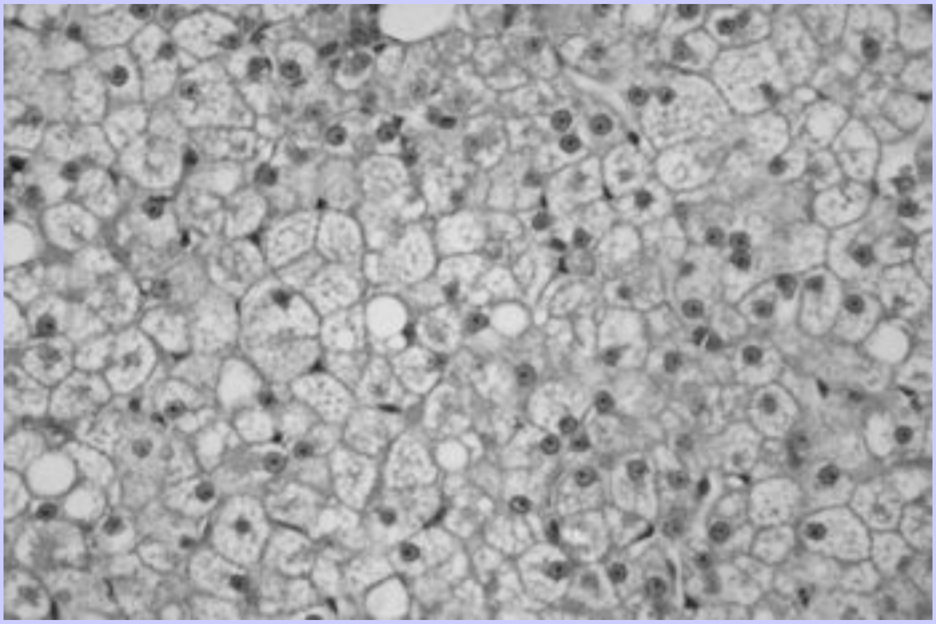


Necropsy findings in affected ponies include widespread fatty change in the liver, skeletal muscle, kidney, adrenal cortex, and myocardium.[60,147] The liver and kidney are enlarged, yellow, friable, and greasy. One of every five ponies with hepatic lipidosis has a ruptured liver.[147] Microscopically, hepatocytes are engorged with lipids. The nucleus often is displaced, and hepatocellular necrosis may ensue.

14.3.1.9.4

Treatment

The major therapeutic objectives for hyperlipemia and hepatic lipidosis include the following:

1. Treatment of hepatic disease
2. Improvement of energy intake and balance
3. Elimination of stress or treatment of concurrent disease
4. Inhibition of fat mobilization from adipose tissue
5. Increased triglyceride uptake by peripheral tissues

Treatment of hepatic failure is addressed elsewhere(see Treatment of Hepatic Insufficiency). Concentrated carbohydrate feed, such as molasses-coated grain and high-quality pasture or hay, should be encouraged. Anorectic ponies should receive 5% dextrose as a continuous infusion at a rate of 2 ml/kg/hr, and enteral nutrition should be attempted. NutriFoal, NutriPrime (KenVet, Ashland, Ohio) and Osmolyte HN (Ross Laboratory, Columbus, Ohio) have been used successfully as sources of enteral nutrition in hyperlipemic Miniature horses. If enteral nutrition is not possible, providing partial parenteral nutrition with equal volumes of 50% dextrose and 8.5% amino acids is recommended.[150] Monitoring blood glucose

concentrations closely is mandatory because some ponies have glucose intolerance, and excessive glucose worsens acidosis and induces hypokalemia. Weaning suckling foals may help reduce stress and the energy demand imposed on lactating mares. One should treat concurrent diseases amenable to therapy appropriately, such as parasitism, chronic infection, and musculoskeletal disease with anthelmintics, antimicrobials, or analgesics, respectively.

In addition to supplying immediate energy, glucose therapy stimulates the release of insulin. Concurrent carbohydrate and insulin administration have been used successfully to manage hyperlipemia in ponies.[146,158] The following regimen has been suggested for a 200-kg pony[158]:

> Day 1: Administer 30 IU of protamine zinc insulin intramuscularly and 100 g of glucose orally, both twice daily.
>
> Day 2: Administer 15 IU of insulin intramuscularly twice daily and 100 g of galactose once.

Galactose is converted slowly to glucose, thus minimizing lactic acid production. This regimen may be continued for 3 days. One should monitor blood glucose and insulin concentrations closely. Insulin treatment may not lower triglyceride levels, but it may help control hyperglycemia if partial parenteral nutrition is provided.[150] Nicotinic acid, thought to act by inhibiting hormone-sensitive lipase, has been used in cattle with fatty liver; however, nicotinic acid has not been evaluated in ponies with hepatic lipidosis.

Heparin potentiates the activity of lipoprotein lipase and may increase triglyceride removal from the blood. However, because lipoprotein lipase activity is already at maximum rate in affected ponies, whether heparin provides additional benefit is questionable.[153] Recommended dosages range from 40 to 250 IU/kg twice daily.[146,158] Because of the potential for hemorrhage, heparin therapy should be used with discretion and monitored daily by hemostatic testing. If azotemia, acidosis, or electrolyte abnormalities are present, appropriate fluid therapy is suggested.

Lipotropic agents such as choline and methionine are unlikely to be useful in horses with hyperlipemia, because triglyceride synthesis in the liver is usually sufficient.

14.3.1.9.5 Prognosis and Client Education

The prognosis for Equidae with hyperlipemia is poor. Mortality has been estimated to occur in 60% to 100% of affected ponies.[146,147] Survival rate is reported to be better in Miniature horses, and death often results from the underlying disease and not fatty liver failure.[150,151] Most Miniature horses with blood triglyceride levels less than 1200 mg/dl survive.[151] Prevention is achieved best by providing appropriate nutrition without inducing obesity, avoiding stress, and practicing good routine health care.

14.3.2 CHRONIC HEPATIC DISEASES

The distinction between acute and chronic hepatic disease is difficult. Horses with chronic liver disease often 981
have abrupt onset of signs. With the possible exception of hyperglobulinemia, no serum biochemical parameters 982
reliably distinguish acute from chronic hepatocellular disease. Regardless of the cause or site of injury, histopathologic evidence of fibrosis develops only after chronic injury.[159] The following diseases are classified

as chronic based on the presence of fibrosis in the liver or because the cause is known to result in gradual hepatic dysfunction.

14.3.2.1 Chronic Megalocytic Hepatopathy

Megalocytic hepatopathy occurs worldwide and is the most common cause of chronic liver failure in horses in certain parts of the United States.[19] The disease is caused by the ingestion of *pyrrolizidine alkaloid*–containing plants. The intoxication typically results in the delayed onset of chronic, progressive liver failure.

14.3.2.1.1 Clinical Signs

The development of clinical signs of liver disease usually is delayed 4 weeks to 12 months following the consumption of pyrrolizidine alkaloid–containing plants. However, individual differences in susceptibility occur, for not all horses consuming the plants develop clinical signs.[160] The onset of obvious hepatic failure, characterized by HE and photosensitization, usually is abrupt and occurs late in the disease despite the time interval since ingestion. Premonitory signs of insidious onset may include anorexia, weight loss, exercise intolerance, and mild to moderate icterus. Diarrhea, edema, polydipsia, pruritus, laryngeal hemiparalysis, and hemolysis also have been reported to occur late in the disease.[66,160,161] Sometimes oral ulcers and halitosis develop.[162] Although uncommon, if sufficient consumption occurs during a single exposure, abortion or clinical signs of liver disease may develop acutely.

14.3.2.1.2 Epidemiology and Pathogenesis

Numerous species of pyrrolizidine alkaloid–containing plants exist (Table 14-3). In the United States, *Senecio jacobaea* and *S. vulgaris* are found primarily along the Pacific Coast and in the western states, *Amsinckia intermedia* in the West, and *Crotalaria sagittalis* (Figure 14-10), *C. spectabilis*, and *Heliotropium europaeum* primarily in the Southeast.

TABLE 14-3 Pyrrolizidine Alkaloid–Containing Plants

SPECIES NAME	COMMON NAME	ALKALOIDS
Senecio jacobaea	Tansy or common ragwort, stinking willie	Jacobine, jacodine, senecionine
Senecio riddellii	Riddell's groundsel	Ridelline
Senecio longilobus	Threadleaf groundsel	Longilobine
Senecio vulgaris	Common groundsel	Senecionine, seneciphylline, retrorsine
Senecio spartioides	Broom groundsel	Seneciphylline
Senecio integerrimus	Lamb's tongue groundsel	Intergerrimine
Amsinckia intermedia	Fiddleneck, fireweed, or tarweed	
Crotalaria species	Rattlebox	Monocrotaline, fulvine, crispatine
Echium plantagineum	Viper's bugloss	
Heliotropium europaeum	Common heliotrope or potato weed	Heliotrine, lasiocarpine

Pyrrolizidine alkaloid–containing plants are not palatable, and horses typically do not consume them unless pastures are contaminated heavily or no alternative feed source exists. Some herbicides may increase palatability.[161] Pyrrolizidine alkaloids are stable, and many intoxications occur following ingestion of contaminated hay, pellets, or grain. *S. vulgaris* is a common contaminant in alfalfa hay, especially at the first cutting. Not all parts of the plant contain pyrrolizidine alkaloids, and the concentration may vary with the season.[163] *Amsinckia* and *Crotalaria* species concentrate pyrrolizidine alkaloids in their seeds; thus intoxication may occur following ingestion of contaminated oat hay or grain screenings.[161]

Horses and cattle are sensitive to pyrrolizidine alkaloid intoxication compared with goats and sheep. Consumption of the plants at a dose of 2% to 5% of the body weight of the horse, fed at one time or over a few days, can result in acute toxicity.[161] The effects of pyrrolizidine alkaloids are cumulative, thus toxicity more commonly occurs following chronic low-level exposure. Hundreds of different pyrrolizidine alkaloids exist, but only a few are proved to be toxic (see Table 14-3). The toxic pyrrolizidine alkaloids vary among plants, but they all cause the same basic lesion. Ingested pyrrolizidine alkaloids are carried to the liver via the portal circulation and are metabolized by the microsomal enzymes to toxic pyrrole derivatives.[162] Drugs that induce microsomal enzymes, such as mixed function oxidases, increase the toxicity of pyrrolizidine alkaloids. The pyrroles are chemically highly reactive and capable of alkylating nucleic acids and protein; consequently, the pyrroles inhibit cellular replication and protein synthesis. Because the cells cannot divide, hepatocytes enlarge, forming *megalocytes*. When the megalocytes die, fibrosis ensues. When fibrosis becomes extensive, the liver shrinks and develops a firm texture and failure is inevitable. 982

Figure 14-10 A *Crotalaria* spp. plant containing toxic pyrrolizidine alkaloids. (Photograph courtesy Susan White.)

Hepatocytes surrounding the portal triads usually are affected first. When acute massive consumption occurs, extensive centrilobular hepatocellular necrosis occurs. Fibrosis around the portal vessels can cause portal hypertension, ascites, and diarrhea. Endothelial cell swelling in the portal vein is especially common with *Crotalaria* species, further promoting venoocclusion. Despite periportal fibrosis and venoocclusion, portal hypertension rarely develops in horses, though it is a common manifestation of pyrrolizidine alkaloid toxicity in cattle.[161] Additional pathologic findings include myocardial necrosis, colitis, widespread hemorrhages, and adrenal cortical hypertrophy.[66] The toxic pyrrolizidine alkaloidin *Crotalaria* species, monocrotaline, also is pneumonotoxic and may cause hydrothorax, pulmonary edema, epithelialization, and pulmonary arteritis.[162]

Pyrrolizidine alkaloids are excreted rapidly in body fluids such as milk and urine, and they can pass the placenta.[162] A report describes pyrrolizidine alkaloid toxicosis in a 2-month-old foal the dam of which consumed pyrrolizidine alkaloid–containing plants during pregnancy.[164]

14.3.2.1.3

Diagnosis

One can make a presumptive diagnosis of megalocytic hepatopathy from history of exposure to pyrrolizidine alkaloids, clinical signs, and laboratory evidence of hepatic disease. Early in the disease, SDH and AST may be increased, but by the time clinical signs develop, these enzymes are often normal or only mildly increased. Because fibrosis occurs periportally, GGT and ALP are increased persistently. Bilirubin may be increased and the BCAA:AAA ratio may be decreased.[165] The BSP half-life is prolonged and serum bile acids usually are increased late in the disease.[66]

A definitive diagnosis of pyrrolizidine alkaloid intoxication requires a liver biopsy. The histopathologic findings of megalocytosis, biliary hyperplasia, and fibrosis are essentially pathognomonic. One may distinguish pyrrolizidine alkalosis from aflatoxicosis and alsike clover *(Trifolium hybridum)* toxicity. The latter two toxicities are rare compared with pyrrolizidine alkaloids and cause periportal fibrosis and biliary epithelial hyperplasia without megalocytosis. Pyrrolizidine alkaloids in feed can be detected by high-performance liquid chromatography.[66] Some pyrrolizidine alkaloids are identifiable in liver tissue. Unfortunately, because of the prolonged delay in development of clinical signs, often the original source of contamination remains unidentified.

14.3.2.1.4 Treatment and Prognosis

No specific antidote for pyrrolizidine alkaloid intoxication exists. Despite general supportive care, death usually occurs within 10 days of the onset of obvious clinical signs of hepatic failure. A serum bile acid concentration greater than 50 μmol/L suggests a grave prognosis. Because regeneration is not possible, if extensive megalocytosis and fibrosis are present, treatment is not warranted. Treatment with BCAAs may decrease the severity of neurologic signs but does not prevent death.[66] If clinical signs or histologic changes are mild, a low-protein (grass or oat hay), high-energy (molasses concentrate grain) ration may be beneficial.

One should direct attention toward asymptomatic horses that also may have consumed the plants. The source of contamination should be identified by locating the plant in hayfields or pasture or by analysis of feed and then should be discontinued. Progress can be monitored by serial liver enzyme quantitation and biopsies. Serum GGT activity may be helpful in detecting subclinical cases of pyrrolizidine alkaloid toxicity.[166]

14.3.2.2 Clover Poisoning

Alsike clover *(Trifolium hybridum)* and red clover *(T. pratense)* poisoning rarely occurs in horses pastured or fed hay containing these types of clover.[167–169] Photodermatitis and liver disease have been reported. Signsof liver disease may become apparent after 2 weeks of consumption and when the diet consists of at least 20% clover.[167] The likelihood of poisoning is reported to be greater when the pasture is covered heavily with the clover in full bloom during wet seasons. Although the toxic principle is not known, the disease is characterized histopathologically by the presence of biliary hyperplasia and periportal fibrosis. Minimal parenchymal lesions distinguish alsike clover poisoning from pyrrolizidine alkaloid toxicity.

14.3.2.3 Chronic Active Hepatitis

Chronic active hepatitis (CAH) in horses is an idiopathic, chronic, progressive hepatopathy characterized histopathologically by biliary hyperplasia, with concomitant periportal or biliary inflammation or both and associated hepatocellular damage. 983 984

14.3.2.3.1
Clinical Signs

The onset of clinical signs of CAH is insidious. Signs are compatible with progressive liver failure and include depression, exercise intolerance, weight loss, anorexia, colic, icterus, and fever. The signs may be intermittent. Although uncommon, some horses with CAH have moist exfoliative coronary dermatitis.[61]

14.3.2.3.2
Cause and Pathogenesis

The exact cause of CAH in horses is not known. A similar syndrome occurs in human beings and has been linked to autoimmune disease, chronic hepatitis B virus infection, non-A, non-B (viral) hepatitis, Wilson's disease, α_1-antitrypsin deficiency, and drug allergy. Human beings with autoimmune-associated CAH often have significant polyclonal gammopathyand hepatic actin, smooth muscle, and antinuclear antibodies.[170] Histologic study of the liver reveals mononuclear and plasma cell infiltrates, large areas of necrosis, and fibrosis. Extrahepatic signs of autoimmune disease, including dermatitis, arthritis, and glomerulonephritis, may be present. Some horses with CAH have polyclonal gammopathy, but this is a nonspecific finding in many types of chronic hepatic disease and does not necessarily indicate autoimmunity. Occasionally, horses with CAH have predominantly plasma and mononuclear cell infiltrates in the liver, suggesting heightened humoral activity. The presence of coronary dermatitis in horses with CAH may be a manifestation of autoimmune disease, though this has not been confirmed by immunohistologic staining. No reports exist of antinuclear antibodies in horseswith CAH, and viral hepatitis, Wilson's disease, andα_1-antitrypsin deficiency have not been documented. Idiosyncratic drug hypersensitivity has been reported in horses, though not as a consistent feature of CAH.

In addition to the possibility of an autoimmune or hypersensitivity reaction, CAH in horses may be a manifestation of chronic cholangitis. Many horses with CAH have a suppurative inflammatory response involving the biliary system, in addition to periportal inflammation and hepatocellular necrosis.[61] Often the cholangiohepatitis is accompanied by biliary hyperplasia, fibrosis, and cholestasis. In some cases, coliform organisms have been isolated from the liver, suggesting ascending infection from the gastrointestinal tract.

A large number of horses have histopathologic evidence of fibrosis, acute inflammation, and hepatocellular necrosis, but no specific cause can be determined.

14.3.2.3.3
Diagnosis

The diagnostic criteria for CAH in human beings include abnormally increased serum transaminase activity for greater than 6 months, abnormal immunologic findings, and characteristic histopathologic findings.[170] In horses, serum SDH and AST activity may be increased mildly, but GGT and ALP often are increased greatly in CAH. The serum bile acid, total protein, and bilirubin (especially the direct reacting fraction) concentrations may be increased. Bilirubinuria may be present, and the BSP half-life usually is prolonged. Hematologic examination may reveal an inflammatory leukogram, with or without a left shift.[61] Immunodiagnostics, including determination of the antinuclear antibody titer and antiimmunoglobulin immunofluorescent staining of skin lesions, may help confirm an autoimmune phenomenon.

In the face of clinical signs and the demonstration of significant laboratory findings indicative of liver disease, one should obtain a liver biopsy (see Liver Biopsy). One should submit a sample for

histopathologic examination and for bacterial isolation and antimicrobial sensitivity testing. The definitive diagnosis of CAH depends on the presence of characteristic histopathologic findings. Progressive periportal hepatocellular necrosis obscures and distorts the limiting plate, the cord of hepatocytes that surrounds the portal triad. As this destructive process continues, bands of necrotic hepatocytes and inflammatory cells connect one liver lobule to another or extend from the portal tract to the central vein. This feature is called *bridging necrosis*. As bridging necrosis progresses, fibrosis and cirrhosis prevail. Mononuclear cells may be the predominant inflammatory infiltrate; however, neutrophils predominate if cholangiohepatitis is a feature. Biliary hyperplasia may be concurrent evidence of cholangiohepatitis.

14.3.2.3.4

Treatment

General supportive care for hepatic failure (see Treatment of Hepatic Insufficiency) is indicated whenever clinical signs are apparent. Specific therapy forCAH depends on the histopathologic findings. If the liver biopsy reveals abundant plasma cells or other diagnostic tests suggest autoimmune or hypersensitivity disease, corticosteroid therapy may be beneficial. In human beings with autoimmune-associated CAH, corticosteroids improve appetite and attitude, reduce inflammation and serum transaminase activity, and hinder fibrosis. Despite short-term improvement, corticosteroids do not alter survival time, and the long-term prognosis remains poor. In horses, initial treatment with dexamethasone at the dose rate of 0.05 to 0.1 mg/kg/day for 4 to 7 days, followed by a gradual reduction in dose rate over 2 to3 weeks, has been suggested.[171] Additional treatment with prednisolone (1 mg/kg/day) may be necessary for several weeks. In human beings, azathioprine (2 mg/kg every 24 hours) also has been used to control cases refractory to steroids.[170]

If the liver biopsy reveals cholangitis, long-term (4to 6 weeks) antimicrobial therapy is indicated. The choice of antimicrobial is determined best by culture and sensitivity results. Antimicrobials that are excreted in bilesuch as chloramphenicol, ceftiofur, ampicillin, or broad-spectrum antimicrobials such as penicillin 984
and gentamicin are recommended. One should consider carefully the decision to provide corticosteroid 985
therapy in these cases of CAH.

14.3.2.3.5

Prognosis

The prognosis for CAH varies depending on the cause and duration of disease. The presence of cirrhosis warrants a grave prognosis.

14.3.2.4

Cholelithiasis

Cholelithiasis, or the formation of biliary calculi, occasionally results in hepatocellular disease in horses. A *cholelith* is a calculus that develops anywhere along the biliary pathway. A *hepatolith* and *choledocholith* refer to calculi within intrahepatic ducts and the common bile duct, respectively. Hepatic failure and clinical signs occur when multiple stones are present or when they occlude the common bile duct.

14.3.2.4.1

Clinical Signs

Cholelithiasis occurs most commonly in adult, middle-aged horses (6 to 15 years old), though horses as young as 3 years old have been affected.[51,124,172] Broodmares may be predisposed to cholelithiasis.[124] The most frequently reported clinical signs include icterus, abdominal pain, fever, depression, and weight loss.

Signs of hepatic failure, such as photosensitization, petechial hemorrhages, diarrhea, and HE, have been reported less frequently.[51,124,172–174] Clinical signs are often intermittent unless the common bile duct is occluded, whereupon persistent abdominal pain prevails.

14.3.2.4.2 Pathogenesis

The initial step in the formation of a cholelith is precipitation or aggregation of normally soluble constituents of bile: bilirubin, cholesterol, or bile acids. In human beings, 75% of bile stones are composed principally of cholesterol and 25% are composed principallyof calcium bilirubinate. Most calcium bilirubinate choleliths in human beings are associated with bacterial cholangitis.[175,176] Most choleliths in horses consist principally of calcium bilirubinate and are associated with cholangitis.[51,124,172]

The exact sequence of events leading to precipitation of bilirubin in bile is not entirely known; however, soluble, conjugated bilirubin becomes unconjugated by the enzyme β-glucuronidase and combines with calcium, a normal constituent of bile, to form calcium bilirubinate. Excessive formation of unconjugated bilirubin causes the formation of columnar complexes of calcium bilirubinate that subsequently precipitate. β-Glucuronidase is synthesized by the bile duct epithelium, hepatocytes, and certain bacteria. The concentration of β-glucuronidase is normally low in bile, plus an inhibitor, glucaro-1,4-lactone, is usually present.

Whether bacterial, biliary, or hepatic in origin, increased bile concentration of β-glucuronidase has been demonstrated in human beings with obstructive cholangitis.[176] Because most choleliths in horses are composed of calcium bilirubinate and many affected horses with cholelithiasis have documented bacterial cholangitis, cholelith formation in horses most likely occurs following bacterial infection. Furthermore, because enteric organisms are isolated most commonly from horses with cholelithiasis, infection presumably ascends from the intestinal tract. Horses may be more prone to ascending infection because they lack an exit port sphincter to prevent backflow of intestinal contents into the biliary tree. If bile flow decreases for any reason, retrograde flow and infection are likely. However, the correlation of infection with cholelithiasis in horses does not necessarily prove causation. Another plausible explanation is that the sequence of events is the initial presence of a stone that precipitates cholestasis and subsequent infection. Despite its origin, cholangitis is the likely cause of fever. Chronic cholestasis caused by the presence of choleliths results in increased biliary pressure, a likely cause of abdominal discomfort. If biliary pressure is not resolved, pressure-induced periportal hepatocellular necrosis with subsequent fibrosis ensues.

At necropsy, tissues are icteric and the liver is mottled. The liver appears enlarged following acute biliary obstruction and shrunken and firm with chronic cholestasis. Choleliths range in size, are single or multiple in number, are usually green-brown (bilirubinate), and have smooth texture. Histopathologic study reveals periportal hepatocellular necrosis, fibrosis, biliary stasis, and biliary hyperplasia. Suppurative cholangitis is often present. Organisms isolated from the liver or bile consist predominantly of gram-negative coliforms, though *Enterococcus* also has been reported.[51,124,172] Nonobstructive choleliths are subclinical and are recognized only at necropsy.

14.3.2.4.3 Diagnosis

One should consider cholelithiasis in the differential diagnosis in any horse with a history of fever, icterus, and abdominal pain, especially if accompanied by signs of hepatic failure. Hematologic examination often reveals leukocytosis caused by mature neutrophilia, especially if cholangitis is present. Other nonspecific

but frequent findings include hyperproteinemia and hyperfibrinogenemia.[51,124,172] The most common abnormal laboratory findings that suggest cholestatic liver disease include greatly increased GGT (greater than 15 times normal); increased serum bile acids concentration; hyperbilirubinemia, with the direct reacting fraction greater than 25% of the total value; and bilirubinuria.[*] Although not liver-specific, ALP often is increased greatly. Less commonly, SDH, arginase, AST, and LDH-5 are increased mildly to moderately, and clotting times and the BSP half-life are prolonged.[51,124,172–174,177] Affected horses frequently have nonseptic peritonitis or peritoneal transudate.[172]

985

986

Figure 14-11 Ultrasound image of the liver showing a hepatolith *(arrow)* casting an acoustic shadow in a dilated bile duct in a horse with obstructive cholelithiasis.

Although no single blood test was specific for cholithiasis, hepatic ultrasonography or biopsy accurately predicted a diagnosis of cholethiasis in all cases reviewed.[172] In retrospective studies of cholelithiasis, 75% of the cases had visibly dilated bile ducts, which appear as thin-walled, anechoic structures.[51,124,172,178] This finding contrasts with normal horses in which the bile ducts are not detectable. A parallel channel sign of biliary dilation in association with dilation of intrahepatic biliary radicals lying adjacent to portal venous structures may be evident.[178] The liver may appear enlarged with increased echogenicity. Hepatoliths, which occur in 60% of cases, are found most frequently at the level of the right sixth to seventh intercostal space,[51,124,172,178] appear as hyperechoic foci within the bile ducts and maycast acoustic shadow (Figure 14-11). Determination of obstruction of the common bile duct in horses is difficult, because the common bile duct is not visible by transabdominal ultrasonography. Hepatobiliary scintigraphy may be useful to document obstruction of biliary excretion.[179] Otherwise, one can detect choledocholiths only via palpation during exploratory celiotomy.

Obtaining a liver biopsy is useful for diagnostic, therapeutic, and prognostic purposes. The histopathologic findings of periportal fibrosis, biliary stasis and hyperplasia, and cholangitis are not pathognomonic for cholelithiasis; however, a liver biopsy may help rule out other causes of biliary stasis such as CAH or megalocytic hepatopathy. Concentric fibrosis around intrahepatic bile ducts is evidence of occlusion of the common bile duct (Figure 14-12).

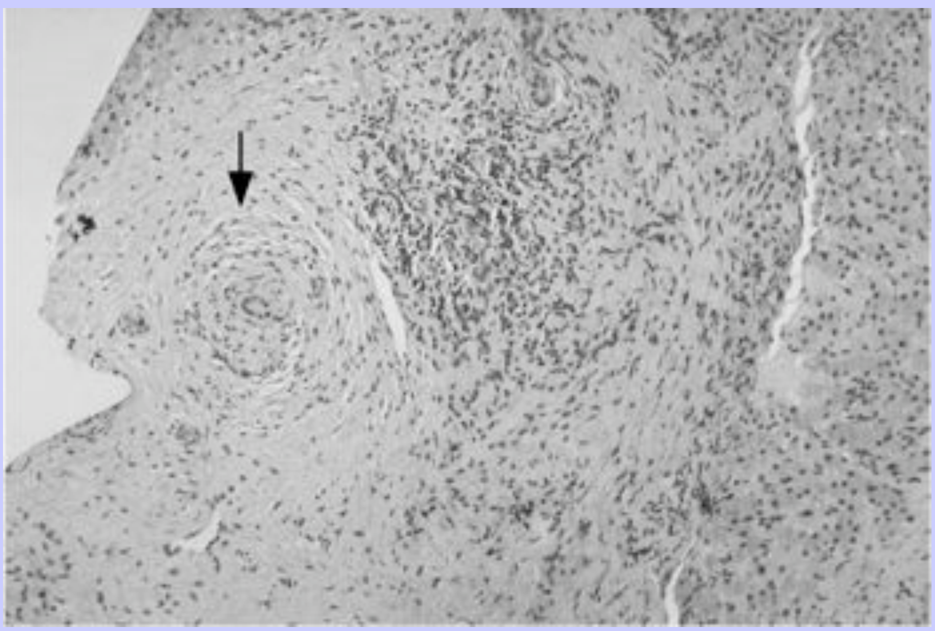
* References 51, 124, 172, 173, 175, 177.

14.3.2.4.4

Treatment

If clinical signs of liver failure are present, one should provide general supportive care (see Treatmentof Hepatic Insufficiency). Long-term (4 to 6 weeks) treatment with antimicrobials is indicated. Antimicrobial selection should be guided by clinical response and by bacterial isolation and sensitivity results obtained via a liverbiopsy or culture of the bile or cholelith obtained at surgery. Penicillin-gentamicin, ceftiofur, chloramphenicol, ampicillin, enrofloxacin, metronidazole, and trimethoprim-sulfonamide have been used successfully[51,124,172]; however, recent reports describe resistance of isolates from affected horses to trimethoprim-sulfonamide.[172] Antimicrobial therapy should continue until complete resolution of clinical signs and laboratory evidence of inflammation. Some have suggested continuing antimicrobial therapy until the serum GGT activity is normal.[124]

Figure 14-12 Histopathology of the liver. Concentric fibrosis *(arrow)* around a bile duct is characteristic of obstruction of the common bile duct.



Dissolution of cholesterol choleliths in human beings has been successful with long-term administration of bile acids.[180] Because choleliths in horses are composed primarily of biliary pigments, treatment with bile acids most likely would be unavailing and potentially harmful. Evidence indicates that dimethyl sulfoxide dissolves calcium bilirubinate stones in human beings, and thusits use may be beneficial to horses with cholelithiasis.[124] Use of other antiinflammatory drugs, such as flunixin meglumine, may help speed resolution of hepatic and biliary inflammation and thus restore biliary excretion.

Surgical intervention may be necessary for occlusion of the common bile duct. The decision for surgery is difficult, because no direct way exists to determine the extent of occlusion of the common bile duct in

horses. In one report, horses with discrete occlusive choledocholiths had persistent fever; more persistent, though mild and intermittent, abdominal pain; and significantly greater serum bile acid concentrations than did horses that were managed successfully with medical therapy.[172] Although cholelithotripsy may be accomplished in human beings percutaneously, via endoscopy or laparotomy, exploratory laparotomy currently is the only available means for reducing a common bile duct obstruction in horses. Choledocholithotripsy (the crushing of choleliths in the bile ducts) and choledochotomy (surgical formation 986

987 of an opening into the bile duct) have been performed in the horse successfully.[175,181,182] In one recent report on horses, external massage of the common bile duct, without choledochotomy, successfully dislodged choledocholiths into the duodenum in all of the cases inwhich it was attempted.[172] If multiple hepatoliths are distributed throughout the biliary tree, these cannot be removed readily by surgery.

14.3.2.4.5 Prognosis

The prognosis of cholelithiasis depends on the extent of hepatic fibrosis, severity of clinical signs, and number and location of choleliths. Extensive or bridging fibrosis, multiple choleliths accompanied by clinical signs of hepatic failure, hepatic atrophy, and severe HE warrant a poor to grave prognosis.[51,124,172] Reports exist of resolution of extensive fibrosis following reestablishment of bile flow, thus one should not consider the presence of extensive fibrosis alone to be lethal.[172,183] In contrast to reports of 30% survival for equine cholelithiasis,[51] recent reviews indicate 77% to 85% survival with medical or medical and surgical treatment.[124,172] If obstruction of the bile duct requires a choledochotomy, the prognosis is guarded because of limited access to the bile duct in a horse and the risk of choleperitoneum.

14.3.2.5 Chronic Cholangiohepatitis and Biliary Fibrosis

Chronic cholangiohepatitis and biliary fibrosis most commonly are associated with CAH, chronic cholangiohepatitis, cholelithiasis, and pancreatitis (see the previous discussion). Liver failure rarely results from primary idiopathic cholangitis or biliary fibrosis.[58] Therapy is supportive. Treatment of bacterial cholangiohepatitis is discussed elsewhere (see Bacterial Hepatitis; Chronic Active Hepatitis; and Cholelithiasis). The prognosis depends on the degree of fibrosis. Extensive fibrosis warrants a poor prognosis, though reports of reversalof hepatic fibrosis exist, especially on relief of the obstruction in cholestatic diseases.[183]

14.3.2.6 Neonatal Acquired Biliary Obstruction

Healing duodenal ulcers located adjacent to the hepatopancreatic ampulla in neonatal foals may result in extrahepatic biliary stenosis.[19,184] Clinical signs are compatible with gastroduodenal obstruction and include reduced suckling reflex, depression, prolonged recumbency, colic, bruxism, and firm feces. Nasogastric intubation often produces voluminous reflux. One may confirm duodenal stenosis radiographically by delayed gastric emptying of barium sulfate. One should suspect biliary stenosis if the serum levels of conjugated bilirubin and GGT are increased or if nuclear scintigraphy indicates delayed biliary excretion. Cholangiohepatitis may develop because of chronic cholestasis and may be confirmed by histopathologic examination of a liver biopsy. One must differentiate acquired biliary stenosis from congenital biliary atresia. Successful surgical correction of acquired biliary stenosis following duodenal stricture has been described.[184]

One should consider chronic cholangiohepatitis without biliary stenosis, another potential sequela to duodenitis or duodenal ulceration, in icteric foals with increased serum conjugated bilirubin and GGT.[19] One confirms the diagnosis by histopathologic examination. Treatment should consist of long-term antimicrobial therapy directed by bacterial isolation and sensitivity results (see Bacterial Hepatitis).

14.3.2.7 Hepatic Abscessation

Liver abscessation is uncommon in horses. Clinical signs of hepatic abscessation depend on the extent and location of the abscess(es); however, abscesses are unlikelyto result in hepatic failure. Small solitary abscesses or multifocal microabscesses usually remain subclinical. Larger abscesses may be accompanied by weight loss, intermittent fever, and anorexia.

Hepatic abscessation in foals may be hematogenousas a sequela to bacteremia or ascending through the umbilical vein as a sequela to omphalophlebitis.[185] In the adult, bacteremia is uncommon, and hepatic infectionor abscessation more likely originates in the intestinal lumen and ascends the bile duct or originates in the intestinal wall or mesenteric lymph nodes and is carried to the liver via the portal blood.[186] The latter is a likely sequela to primary abdominal or mesenteric abscessation caused by *Streptococcus equi*. In one retrospective study of abdominal abscesses in horses, only 2 of 25 horses had solely hepatic abscesses, though some horses had abscesses involving several abdominal structures.[187]

Laboratory diagnosis of hepatic abscessation is difficult. Smaller abscesses may not result in sufficient hepatocellular damage to impede liver function. Laboratory abnormalities characteristic of chronic inflammation and infection, including anemia of chronic disease, hyperfibrinogenemia, hypergammaglobulinemia, and mature neutrophilia, may occur with larger abscesses. Increased serum activity of liver-specific cytosolic enzymes or bile acids rarely occurs unless liver abscessation is extensive. Ultrasonography of the liver may reveal focal hyperechoic or hypoechoic areas.[186] A liver biopsy should be guided by ultrasound to avoid penetration of the abscess. One should direct long-term antimicrobial therapy by culture and sensitivity results. Common isolates from abdominal abscesses in horses include *S. equi, S. zooepidemicus*, and *Corynebacterium pseudotuberculosis*.[187]

14.3.2.8 Hepatic Neoplasia

Primary hepatic neoplasia is rare in horses. A retrospective survey in 1952 indicated that hepatic tumors 987
accounted for only 1% of all equine neoplasms.[188] Of the documented primary hepatic neoplasms in horses 988
(cholangiocarcinoma, hepatocellular carcinoma, hepatoblastoma, and mixed hamartoma), cholangiocarcinoma is the most common.[59,87,88,188–192] Hepatic neoplasia in horses is more likely to occur following metastasis of some other primary tumor, especially lymphosarcoma.[89] Because clinical signs of hepatic failure usually are not apparent and laboratory findings are nonspecifically indicative of chronic inflammatory disease, antemortem diagnosis of hepatic neoplasia is difficult.

In one report, *cholangiocarcinoma* accounted for 9of 10 primary liver neoplasms in horses.[188] Cholangiocarcinoma originates from the bile duct epithelium and is distinguished from hepatocellular carcinoma by its tendency to form multiple foci, its firm texture, and a whitish color produced by abundant fibrous stroma. The primary mass is typically solitary, with multiple intrahepatic secondaries. Extrahepatic metastasis is common with transperitoneal lymphatic spread to the peritoneum and diaphragm and

hematogenous spread to the lungs. In human beings, dogs, and cats, an etiologic relationship exists with liver fluke infestation or a history of biliary tract disease.[190] A report describes cholangiocarcinoma in a horse after treatment for prolonged septic cholangiohepatitis.[179] Aberrant expression of the protein products of the tumor suppressor gene, p53, was reported at necropsy in one horse with cholangiocarcinoma.[193] Loss of function of p53 has been described in other types of carcinomata and may have contributed to malignancy. Microscopically, cholangiocarcinoma is adenocarcinomatous, producing cuboidal or columnar-lined ductules and acini. The neoplastic bile ducts do not contain bile but may contain mucus.

The clinical presentation and progression of cholangiocarcinoma in horses is not well documented but appears to be more common in older horses.[188] One case report describes a 10-year-old mixed-breed horse in which the presenting signs included anorexia, weight loss, pyrexia, mild icterus, tachypnea, severe dependent edema, and abdominal distention.[192] Abnormal clinicopathologic findings included mature neutrophilia; hyperfibrinogenemia; anemia; moderately increased serum bilirubin, GGT, and SDH; and nonseptic peritonitis and pleuritis. Neoplastic cells were not detected in the body cavity effusions. Definitive antemortem diagnosis of cholangiocarcinoma was made by histopathologic examination of a liver biopsy. Necropsy revealed multiple extrahepatic metastases, including the serosal surfaces of the intestine and spleen, diaphragm, omentum, pleural surfaces, and lung.

Hepatocellular carcinoma, or hepatoma, has been reported in several horses, most of which were less than 3 years of age.[86–88,191] Hepatocellular carcinomata are usually solitary and multilobulated. Extrahepatic metastasis occurs transperitoneally and hematogenously to lungs. Microscopically, the neoplastic cells resemble hepatocytes and retain cord arrangement. However, the normal liver architecture is lost, and sometimes the cells are difficult to differentiate. Mitotic figures are uncommon. Possible etiologic factors in other species include heredity, parasitism, chemical and plant carcinogens, and viral hepatitis.[190]

Reported clinical signs of hepatocellular carcinomain horses include depression, anorexia, weight loss, intermittent diarrhea, and abdominal distention.[86–88,191] Abnormal laboratory findings included absolute erythrocytosis, persistent hypoglycemia, sanguineous peritoneal effusion, and increased serum SDH, GGT, ALP, and indirect reacting bilirubin. In one case, absolute erythrocytosis was attributed to erythropoietin secretion by the carcinoma (inappropriate secondary erythrocytosis).[88] The same horse had a high serum concentration ofα-fetoprotein, a globulin normally synthesized only by embryonic fetal liver cells that is commonly detectable in human patients with hepatocellular carcinoma.

Two case reports describe malignant *hepatoblastoma* in young horses.[59,194] Hepatoblastoma is an embryonic tumor of the liver with a wide range of histologic patterns that include epithelial and mesenchymal elements. Clinical signs included emaciation, pyrexia, and pleural effusion. Laboratory abnormalities included mature neutrophilia, erythrocytosis with normal erythropoietin levels, hypergammaglobulinemia, hyperfibrinogenemia, and increased serum activity of GGT and ASP. In one of the cases, transabdominal ultrasonography identified abnormal hepatic architecture. Increased serum α-fetoprotein may serve as a tumor marker but cannot be used alone to confirm a diagnosis.[194]

A *mixed hamartoma* was described in the liver of a late-term aborted equine fetus.[189] Histologically, the lesion appeared to be a proliferation of large hepatocyte-like cells with eccentric nuclei and voluminous cytoplasm; abnormal bile ducts; and fibroblastic fibrocystic interstitial tissue, with complete lack of structural organization.

14.3.2.9 Hepatic Amyloidosis

Amyloidosis refers to a group of diseases characterized by the extracellular deposition of a proteinaceous fibril substance, *amyloid*, in the tissues. Amyloid deposits are composed of nonbranching fibrils in β-pleated sheet conformation formed by the proteolytic cleavage of precursor proteins by the mononuclear phagocyte system. Depending on the organ of deposition, amyloid distorts normal tissue architecture and may lead to functional impairment. In horses the liver and spleen are the most common organs involved in systemic amyloidosis.[195] Two forms of systemic amyloidosis exist and are distinguished by the type of precursor protein and 988
subsequent protein fibril. The precursor in *reactive* or *secondary* systemic amyloidosis is serum amyloid 989
protein AA, an acute phase protein produced by hepatocytes in response to chronic infection or inflammation. The AA fibrils are identified in tissues by green birefringence in polarized light, after staining with Congo red, which is lost after treatment with potassium permanganate. Most often in horses, hepatic amyloid deposits are AA fibrils andhave been associated with severe parasitism or chronic infection and inflammation.[195,196] One horse in which the liver was the principal organ of amyloid deposition presented for evaluation of chronic weight loss.[196] An antemortem diagnosis of hepatic amyloidosis was not made; however, laboratory abnormalities included severe hypoalbuminemia, polyclonal gammopathy, and large numbers of ascarid and strongylid eggs in the feces. Histopathologically, the liver revealed extracellular deposits of AA amyloid periportally and adjacent to the sinusoids in the space of Disse. The amyloid deposits were accompanied by hepatocytic atrophy and a mild mononuclear cell infiltrate.

Systemic primary, immunocytic, or *idiopathic amyloidosis* is caused by the deposition of amyloid light chain fibrils. The precursor proteins in primary amyloidosis are the variable region of immunoglobulin light chains. The amyloid fibrils also stain with Congo red, but staining is retained after potassium permanganate treatment. *Local immunocytic amyloidosis*, with deposition in the upper respiratory mucosa or skin, is more common in horses than systemic primary amyloidosis. However, at least one reported case describes systemic primary amyloidosis ina 14-year-old Thoroughbred mare with chronic weight loss and cutaneous nodules.[197] Amyloid deposits were identified in the liver, myocardium, spleen, gastrointestinal mucosa, pulmonary interstitium, pancreas, and arterial walls.

14.3.2.10 Chronic Hypoxemia

Right-sided heart failure causes the pressure in the caudal vena cava to rise. Retrograde pressure increases in the hepatic central veins cause hypoxemia and pressure necrosis of the adjacent hepatocytes. Chronic passive congestion may cause fatty change, atrophy, and fibrosis.

14.3.3 CONGENITAL ABNORMALITIES

14.3.3.1 Portosystemic Shunt

Portosystemic shunts may be intrahepatic or extrahepatic, congenital or acquired. Few reports have documented congenital extrahepatic portosystemic shunts in foals.[90,198] The vascular shunts allow blood within the portal system to bypass the liver and drain into the systemic circulation, directly or indirectly, via the caudal vena cava or the azygous vein. In the reported cases, age at presentation varied between 2 and 6 months. Vague intermittent neurologic signs of blindness, ataxia, and severe depression were consistent with

HE. Growth appeared to be stunted. These clinical signs are caused by the altered hepatic blood flow and hepatic insufficiency following hepatocellular atrophy.

Laboratory abnormalities in the reported cases varied, but the most consistent findings included a decreased BUN, prolonged BSP half-life, and increased blood ammonia concentration. Liver biopsies revealed hepatocellular atrophy and necrosis, fibrosis, and biliary hyperplasia.[90] Antemortem diagnosis was confirmed by operative mesenteric portography or nuclear scintigraphy (see Diagnostic Imaging of the Liver). Surgical correction was attempted unsuccessfully in one case.[199] Necropsy examination revealed small, firm livers. The location of the shunt(s) in reported cases varied, but all were extrahepatic, involving a direct connection between the mesenteric veins and the caudal vena cava. Alzheimer's type II astrocytes were visible in the brain in one case and were consistent with HE.[198]

Acquired portosystemic shunts are rare in horses. One report describes an 11-year-old Thoroughbred withHE. The horse subsequently was determined to have a functional portosystemic shunt following vascular thrombosis of the portal vein.[199]

14.3.3.2 Biliary Atresia

At least two cases of extrahepatic biliary atresia in foals have been documented.[200,201] An antemortem diagnosis was not possible in either case; however, veterinary attention was sought at 4 weeks of age in both foals for anorexia, depression, lethargy, poor weight gain, colic, polydipsia, polyuria, pyrexia, and icterus. Laboratory evaluation of one of the foals was consistent with biliary obstruction, as indicated by a mildly increased serum activity of SDH and greatly increased activity of GGT and conjugated bilirubin. Necropsy of both foals revealed a large, firm liver. Although not specifically documented in one case, the entrance to the bile duct and the main bile duct were absent in the other foal.[200] Histologically, both livers appeared similar and consistent with extrahepatic biliary atresia. Bile canaliculi were present and distended, with associated degenerative hepatocytes. Biliary proliferation was extensive and surrounded by fibrous tissue with interdispersed islands of hepatocytes. No bile was in the proliferative bile ducts, and the portal triad ducts were absent.

In horses, extrahepatic biliary atresia is speculated to be congenital. In human beings, other causes suggested include neonatal sclerosing cholangiohepatitis, excretion of a biliary toxin, deficit of bile flow in utero, or lumen destruction caused by ductal vascular insufficiency.[201] Despite the cause, extrahepatic biliary atresia 989
induces intrahepatic biliary hypertrophy, an abortive attempt to establish continuity. The biliary hypertrophy 990
displaces hepatocytes, causing periportal and perilobular hepatocellular degeneration, fibrous replacement, and ultimately loss of normal hepatic architecture. Although an antemortem diagnosis was not possible in either equine case, hepatobiliary scintigraphy (see Diagnostic Imaging of the Liver) successfully detected total biliary obstruction in a neonatal lamb with biliary atresia.[91]

14.3.3.3 Serous Cysts

Serous hepatic cysts have been reported and usually are an incidental finding at necropsy.[14]

15 CHAPTER 15 EQUINE OPHTHALMOLOGY

David A. Wilkie

15.1 Examination

The equine eye presents particular challenges for diagnostic and therapeutic approaches. However, the basic principles of a complete ophthalmic examination hold true. Box 15-1 lists the equipment required for a routine ophthalmic examination. One should perform the initial ophthalmic examination in a well-lighted environment and before tranquilization. The examiner assesses facial, orbital, and eyelid symmetry; looks for ocular discharge (serous, mucoid, mucopurulent) or blepharospasm; and evaluates the cranial nerves, specifically cranial nerves II through VII. A complete ophthalmic examination includes assessment of pupillary light and menace response, maze testing, globe position and mobility, sensation of ocular and adnexal structures, and eyelid position and function. To evaluate direct and consensual pupillary light responses accurately often requires a bright focal light source (3.5-V halogen) and a darkened examination area.

Further examination or therapy may require some form of tranquilization, regional nerve blocks, and topical anesthesia. Detomidine (Dormosedan, Pfizer Animal Health, Exton, Pennsylvania) administered intravenously at 0.01 to 0.02 mg/kg or xylazine (Rompun, Haver-Lockhart, Shawnee, Kansas) at 0.5 to 1.0 mg/kg combined with butorphanol tartrate (Torbugesic, Bristol Laboratories, Inc., Evansville, Indiana) at 0.01 mg/kg administered intravenously provide a synergistic analgesic effect and facilitate examination, sample collection, nasolacrimal irrigation, lavage tube placement, and minor surgical procedures. If one intends to determine intraocular pressure (IOP), one should note that intravenous administration of xylazine significantly lowers the IOP.[1]

Sensory innervation of the globe and adnexa is from the trigeminal nerve (cranial nerve V), and motor innervation is from the facial nerve (cranial nerve VII). The ophthalmic nerves blocked most frequently are the auriculopalpebral branch of cranial nerve VII and the supraorbital (frontal) branch of cranial nerve V. Blocking of these nerves provides akinesia and anesthesia of the superior eyelid, respectively. One can palpate the auriculopalpebral nerve as it courses over the zygomatic arch in the area of the temporofrontal suture. Using a 25-gauge, ⅝-inch needle, one blocks the nerve by injecting 3 to 5 ml of mepivacaine (Carbocaine, Winthrop Laboratories, New York) over the zygomatic arch in this area. One blocks the supraorbital nerve as it emerges from the supraorbital foramen of the frontal bone by palpating the foramen, inserting a 25-gauge, ⅝-inch needle into the foramen, and injecting 2.0 ml of mepivacaine; one infuses another 2 to 3 ml subcutaneously while removing the needle. Additional sensory nerves one occasionally blocks include the infratrochlear, lacrimal, and zygomatic branches of cranial nerve V.[2] Alternatively, one can use local infiltration of anesthetic to provide anesthesia of a specific area.

One now can perform a complete ophthalmic examination (see Box 15-1). One should obtain samples for bacterial or fungal culture or evaluation of tear production before instilling any topical solution or ointment on the eye. One measures aqueous production of tears using commercially available Schirmer tear test strips, with normal wetting being 20 mm or greater in 30 seconds. Using a bright focal light source, one now examines the conjunctiva, nictitans, cornea, anterior chamber, iris, pupil, and lens. One evaluates the ocular media (cornea, aqueous humor, lens, and vitreous) for clarity and transparency; assesses the position and size of the lens, shape 995
996 and mobility of the pupil, and appearance of the corpora nigra; and examines the eye for irregularities, vascularization, and pigmentation. Although one can examine the whole anterior segment using a Finoff transilluminator with or without magnification, a new handheld monocular slitlamp that attaches to an otoscope or

ophthalmoscope handle is available (HSL-10, Heine, United States). The handheld lamp provides magnification and an appreciation for depth and three-dimensional anatomy. Fluorescein staining of the cornea detects the presence of corneal ulceration, and the appearance of fluorescein at the nares indicates a patent nasolacrimal system. Following instillation of topical anesthesia (proparacaine 0.5%, Alcaine, Alcon Laboratories, Fort Worth, Texas), one can cannulate the nasolacrimal puncta using a 3.5F urinary catheter, and irrigate the nasolacrimal system. Alternatively, one can irrigate the nasolacrimal system in retrograde fashion, cannulating the duct using a 5F catheter at the nasal opening. Using thumb forceps, one can grasp the nictitans and examine the palpebral and bulbar surfaces for foreign bodies, mass lesions, or other abnormalities. One collects conjunctival and corneal cells for cytologic study using a Kimura spatula following topical anesthesia. If available, one can use the Tonopen (Mentor O&O, Norwell, Massachusetts) to determine ocular pressure.

15.1.1

BOX 15-1 EQUIPMENT FOR BASIC EQUINEOPHTHALMIC EXAMINATION

Bright, focal light source: 3.5-V halogen light with Finoff illuminator

Direct ophthalmoscope

Indirect 20-D 5× lens

Handheld slitlamp: HSL-10 attaches to direct ophthal-moscope handle (Heine, United States)

Magnifying loupe, 2×-4×

Dressing forceps

Open-ended urinary catheter (3.5 French) for nasolacrimal catheterization

No. 5 French catheter for cannulation of nasolacrimal duct at nares

Sterile fluorescein strips

Schirmer tear test strips

Sterile culture swabs

Kimura spatula for obtaining cytologic sample

Glass slides

Sterile eyewash

Proparacaine 0.5% (Alcaine): topical anesthetic

Tropicamide 1% (Mydriacyl): short-acting dilating agent

Sedation: Xylazine (Rompun)

Butorphanol tartrate (Torbugesic)

Mepivacaine (Carbocaine): local nerve blocks

Modified from Wilkie DA: Ophthalmic procedures and surgery in the standing horse, *Vet Clin North Am Equine Pract* 7:535-547, 1991.

To examine the posterior segments of the eye (optic nerve, retinal blood vessels, and tapetal and nontapetal fundus), one should perform direct and indirect ophthalmoscopy. A new monocular indirect ophthalmoscope, the PanOptic ophthalmoscope (Welch Allyn) allows those more familiar with the technique of direct examination to perform indirect ophthalmoscopy. One evaluates the size and color of the optic nerve, number and size of retinal blood vessels, pigmentation of the nontapetal fundus, and the presence or absence of hypo- or hyperreflective changes of the tapetal fundus.

15.2 Ocular Ultrasonography

15.2.1 TECHNIQUE

One can perform ocular ultrasonography directly through the cornea or the eyelids or by using an offset device. The optimal transducer for ocular ultrasonography is the 10-MHz probe, but one can use a 7.5-MHz probe. Sedation, auriculopalpebral nerve block, and topical anesthesia generally are required. Sterile, water-soluble lubricating jelly works well as a contact material, provided one irrigates the cornea afterward.

15.2.2 NORMAL ANATOMY

Unless one uses an offset device, the cornea and a portion of the anterior chamber are lost in the near artifact. The anterior and posterior lens capsules are visible as an echodense line at the 12 and 6 o'clock positions, whereas the remainder of the lens is anechoic. The iris, corpora nigra and ciliary body are often visible. The vitreous body is normally anechoic. The posterior eye wall is visible as a concave echodensity with the optic nerve head visisble as an echodense area at the posterior pole with an anechoic optic nerve posteriorly. One can visualize the orbital contents best using a 7.5-MHz transducer to evaluate the extraocular muscle cone, optic nerve, and associated structures.

15.2.3 INDICATIONS

Ocular ultrasound is indicated for evaluation of intraocular contents when one or more of the ocular transmitting media are opaque, including opacification of the cornea, aqueous and vitreous humors, and the lens. The most common indications for ocular ultrasound are in eyes with a cataract to evaluate for a retinal detachment, following traumatic hyphema to assess posterior segment damage, or in eyes with severe corneal opacification. In addition, one can evaluate the orbit in instances of exophthalmos or orbital trauma. 996

997

15.3 Eyelids

15.3.1 CONGENITAL

Diseases of the equine eyelid are common. Congenital lesions include coloboma, agenesis, dermoid, and entropion.[3,4] Of these, entropion is the only frequently occurring disease. Entropion is inward rolling of the eyelid margin that results in facial hairs contacting the cornea, leading to irritation, conjunctivitis, and possibly secondary corneal ulceration. Causes include premature or dehydrated foals with enophthalmos, ocular pain

resulting in spastic entropion, and primary conformational problems. Manual reduction and frequent topical ocular lubrication with artificial tear ointment is the initial treatment of choice and may be the only treatment required in some foals, especially if the entropion follows dehydration. If the entropion is severe or does not respond to manipulation, one may place two or three vertical temporary everting mattress sutures to position the eyelid correctly.[3] One must take care to avoid overcorrection and the inability to close the eyelids during blinking. Suture placement is at and perpendicular to the eyelid margin, tacking this to the periocular skin over the orbital rim. Monofilament, 3–0 to 5–0 nylon suture is preferrable; one removes the sutures after 10 to 14 days. One must treat associated corneal disease to prevent secondary infection and subsequent scar formation. Entropion requiring more aggressive surgical intervention in the form of skin excision is rare. Severe or recurrent entropion is correctable by excising an elliptic portion of eyelid skin in the affected area and reapposing the skin edges (Hotz-Celsus procedure).

15.3.2 ACQUIRED

Common acquired conditions involving the equine eyelid include trauma and neoplasia.

15.3.2.1 Trauma

Eyelid trauma includes contusions and lacerations.[5] Commonly associated with eyelid trauma are corneal abrasions or lacerations, anterior uveitis, and if the trauma involves the medial canthus, nasolacrimal system damage. Eyelid contusions often result in blepharoedema and hemorrhage. Although blepharoedema does not require therapy, one can hasten recovery by using systemic flunixin meglumine (Banamine, Schering Corp., Kenilworth, New Jersey), cold compresses in the acute phase, and warm compresses beginning the day following the injury.

Eyelid lacerations are more serious and usually require immediate therapy. The vascular supply to the eyelid is extensive, and many apparent avascular segments of eyelid recover following repair. If possible, primary wound closure is preferrable. One must remove all debris from the wound before closure, disinfect the eyelid surface and adjacent tissues with a 1:25 to 1:50 dilution of povidone-iodine solution, avoid excessive tissue debridement, and under no circumstances amputate a pedicle of eyelid. Loss of eyelid margin, whether through trauma or iatrogenic, results in severe, chronic corneal irritation, vascularization, ulceration, and fibrosis. In addition, reconstructing an eyelid margin from the adjacent skin following amputation of the normal eyelid margin is difficult.

One should suture lacerated eyelids using a two-layer closure, ensuring accurate anatomic apposition of the wound edges and eyelid margin. One can perform minor surgical repairs using sedation and local nerve blocks, but the horse may require general anesthesia if the injury is severe. One sutures the deeper, conjunctival layer first using 4-0 to 6-0 absorbable suture in a horizontal mattress pattern beginning away from and working toward the eyelid margin, taking care to avoid penetrating the conjunctiva so that the suture does not contact the cornea. One then closes the skin with 4–0 to 6–0 nonabsorbable suture. The eyelid margin is the most important part of wound closure and is closed first to ensure accurate apposition. The author prefers to use a cruciate suture pattern at the eyelid margin and a simple interrupted pattern for the remainder of the skin closure. Failure to perform a two-layer closure or achieve precise apposition of the eyelid margin may result in ulcerative keratitis or other secondary complications.[6] Postoperative therapy includes administration antibiotics for 5 to 7 days for systemic effect, tetanus toxoid, warm moist compresses, and flunixin meglumine if inflammation and swelling are a problem. Topical medication is not required for eyelid injuries unless corneal or anterior segment damage accompanies the injury. One must

evaluate eyelid function, and the eyelid must provide adequate protection to the cornea. If the blink response is impaired, one should protect the cornea with topical lubricants as often as possible. Advanced blepharoplastic techniques for repair of severe eyelid trauma with resulting loss of tissue are beyond the scope of this chapter but are discussed in detail elsewhere.[3]

15.3.2.2 Neoplasia

The most common neoplasms of the equine eyelid are sarcoid and squamous cell carcinoma. In addition, melanoma, mast cell tumor, lymphosarcoma, basal cell carcinoma, and papilloma can affect the eyelid. The differential diagnosis for eyelid neoplasms includes parasitic diseases such as ocular habronemiasis and other causes of granulomatous skin disease. Treatment of eyelid neoplasia depends on the location, size, tumor type, age and purpose of the horse, cost, surgical skill, and equipment available. Treatment modalities 997
include surgical excision, radiation therapy, chemotherapy, hyperthermia, immunotherapy, cryosurgery, or a 998
combination of these. The aim of therapy is to eliminate or halt progression of the tumor while maintaining eyelid function and preserving the eye and vision. Complete excision with primary closure is the optimal treatment but often cannot be achieved because of limitations on availability of tissue for reconstruction and the extensive and aggressive nature of many eyelid neoplasms. If one cannot appose eyelid margins following tumor excision, more involved blepharoplastic techniques, such as advancement skin flaps, may be indicated (Figure 15-1).

Figure 15-1 Squamous cell carcinoma involving the medial canthus and inferior eyelid of 19-year-old Appaloosa.

15.3.2.2.1

Squamous Cell Carcinoma

Squamous cell carcinoma involving the eyelid is usually erosive and ulcerative.[7] The medial canthus is the most common site of origin (see Figure 15-1). Invasion of adjacent soft and bony orbital tissue is possible, if untreated. Treatment of ocular squamous cell carcinoma is discussed in detail under Conjunctiva and Third Eyelid.

15.3.2.2.2

Sarcoid

Periocular sarcoid is the second most common eyelid neoplasm of the horse. The average age of an affected horse is 4 years, and smooth and warty sarcoids occur. Orbital invasion and bony involvement are possible. Surgical excision is associated with frequent recurrence and often is combined with cryosurgery, hyperthermia, chemotherapy, or irradiation to ensure complete tumor destruction. Of all treatment modalities, radiation is the most expensive and yields the best overall success.[8]

Intralesional immunotherapy with cell wall extracts of bacille Calmette-Guérin (BCG) in oil has been used effectively in repeated injections 3 weeks apart. A total of four doses usually is required for complete tumor regression with the overall response reported to be 69%, provided the injection was intralesional.[8] Injection of cell wall extracts of BCG is associated with local inflammation and tumor necrosis. During this period of inflammation, one must protect the globe to prevent corneal desiccation or ulceration. The use of live BCG organisms or whole killed organisms has been associated with anaphylactic reaction and death and is discouraged. Adverse systemic reactions to cell wall extracts of BCG are rare, but premedication with systemic corticosteroids is advised.

Intralesional chemotherapy with cisplatin in an oil-water emulsion has been reported to result in regression of equine sarcoid.[9] A series of four injections, spaced 2 weeks apart, with a mean dose of cisplatin of 0.97 mg/cm^3 of tumor mass resulted in tumor regression in all treated horses. In addition, 87% of horses treated for sarcoids were relapse free at a 1-year follow-up.

15.4

Conjunctiva And Third Eyelid

The conjunctiva is divided into bulbar and palpebral surfaces. The conjunctiva merges with the cornea at the limbus, with the eyelid at the eyelid margin, and the bulbar and palpebral conjunctiva join to form the fornix. The conjunctiva has normal resident bacterial and fungal populations. The most common isolates from the equine conjunctiva vary according to geography, season of the year, and investigator.[10–12] In general, isolates of gram-positive organisms—*Corynebacterium, Bacillus, Staphylococcus,* and *Streptomyces*—are more common than gram-negative organisms from normal equine conjunctiva.[11] Fungi are isolated more commonly in the summer and autumn and have been reported to be present in 95% of normal horse conjunctiva samples.[12] In addition, fungi are isolated more frequently from stabled horses, which likely relates to the immediate environmental and husbandry conditions.[11]

Congenital diseases of the equine conjunctiva are uncommon, conjunctival dermoid being the most common congenital abnormality. A dermoid is a congenital tumor of skin and associated glands, hair, and hair follicles that can affect the cornea and adjacent conjunctiva. One should remove a dermoid that is irritating the globe or adnexa surgically by superficial keratectomy/conjunctivectomy.

Unlike the small animal patient, infectious conjunctivitis is rare in the horse. Organisms reported to result in infectious conjunctivitis in the horse include equine herpesvirus type 2,[13] *Mycoplasma* species, *Chlamydia, Moraxella equi,* and mycotic and viral agents.[3]

Foreign bodies and trauma are a common cause of conjunctival irritation and damage and often are associated with concurrent eyelid and corneal injuries. One directs treatment to eliminate the cause, treat any conjunctival or associated eyelid or corneal damage, and prevent secondary infection. One must perform a complete ophthalmic 998
examination in all animals with evidence of ocular trauma. One should consider conjunctival foreign bodies in 999
any horse with a recurrent corneal erosion, ocular pain, or conjunctivitis. One should examine the superior and inferior fornices and the bulbar and palpebral surface of the nictitans following topical administration of 0.5% proparacaine. Magnification is essential to detect foreign bodies. In addition, irrigation of the nasolacrimal system may yield foreign material associated with chronic conjunctivitis or dacryocystitis.

Severe chemosis with conjunctival prolapse and exposure may result from self-trauma, especially associated with being recumbent for a prolonged time. Treatment includes systemic antiinflammatory drugs, artificial tear ointment to protect exposed conjunctiva, keeping the head elevated, and in severe cases, repositioning the conjunctiva and a temporary tarsorraphy until the swelling resolves.

15.4.1 PARASITES

Common parasites of the equine conjunctiva include *Thelazia lacrymalis, Habronema* species, and *Onchocerca cervicalis*.[14] In a necropsy sample the prevalence of *Thelazia* in the conjunctival sac of horses is highest in young animals, with 43% of 1- to 4-year-old horses being affected.[15] In most instances, infection is not associated with clinical signs, but a chronic conjunctivitis, seromucoid discharge, and conjunctival nodules can occur.[3] The adult parasite may be visible on ophthalmic examination of the cornea and conjunctival fornix, and larvae may be visible on examination of centrifuged samples of nasolacrimal washes. Treatment includes removal of the adult worms, irrigation of the nasolacrimal system, topical corticosteroids to control inflammation, and fly control. The topical organophosphates echothiophate, 0.03% to 0.06% every 12 hours, or isoflurophate, 0.025% every 24 hours for 7 days, have been reported to kill the parasite.[16] Systemic treatment with fenbendazole at 10 mg/kg orally every 24 hours for 5 days also is reported to *Thelazia* effectively.[17]

Ocular manifestations of equine cutaneous habronemiasis result when the house or stable fly deposits the larvae of the *Habronema* spp. on or around the eye.[3,18,19] The resulting granuloma is associated with inflammation, intense pruritus, and epiphora. Yellow, caseous granules are notable throughout the granulation tissue. Histologically, eosinophils and mast cells predominate. Diagnosis is based on clinical signs, location, season of the year, and histologic findings. Clinical appearance can simulate squamous cell carcinoma. Histologically, the differential diagnosis is equine cutaneous mastocytosis.[3,19] Ocular lesions are most common at the medial canthus and may involve the skin, nasolacrimal duct, third eyelid, or conjunctiva. Treatment of equine cutaneous habronemiasis varies, and no single treatment is routinely successful.[18] Surgical excision, cryosurgery, local and systemic corticosteroid therapy, systemic ivermectin (single dose, 0.2 mg/kg intramuscularly), various larvicidal treatments in the form of topical and systemic organophosphates, and various topical formulations containing ronnel or metrifonate with a dimethyl sulfoxide vehicle are used[3,18,19] (Table 15-1). Dimethyl sulfoxide serves as a vehicle and has antiinflammatory effects, possibly related to its ability to detoxify hydroxyl radicals generated by neutrophils. The aim of therapy is to kill the larvae while

controlling the resulting inflammation. In addition, fly control is an essential part of an overall management program.

TABLE 15-1 Topical Preparations Used to Treat Equine Cutaneous Habronemiasis

INGREDIENTS	AMOUNT
Ronnel solution (33%)[12]	60 ml
Thiabendazole (33%)[12]	120 g
9-Fluoroprednisolone acetate[12]	60 mg
Dimethyl phthalate (24%)[12]	30 ml
Dimethyl sulfoxide[12]	500 ml
Nitrofurantoin ointment[13]	225 g
Ronnel solution[13]	20 ml
Dimethyl sulfoxide[13]	20 ml
Dexamethasone solution[13]	20 ml
Nitrofurazone ointment (0.2%)[14]	135 g
Trichlorfon (12.3%)[14]	30 ml
Dexamethasone (2 mg/ml) [14]	30 ml
Dimethyl sulfoxide[14]	30 ml

The blood-sucking midge *Culicoides nubeculosus* transmits *O. cervicalis* microfilariae. After transmission, the immature microfilariae migrate through lymphatics and can travel to ocular and adnexal tissues. The prevalence of equine onchocerciasis increases with age, with an overall prevalence of 50% to 60%.[14,20–22] The prevalence of onchocerciasis on histologic examination of the lateral bulbar conjunctiva is 10.8%. The presence of conjunctival microfilaria does not correlate with clinical abnormalities. Ocular onchocerciasis has been proposed as a cause of keratitis, conjunctivitis, equine recurrent uveitis, and depigmentation of the temporal bulbar conjunctiva.[22] The pathogenesis is thought to involve the death of the microfilariae, release of antigens, and development of hypersensitivity in susceptible horses. Treatment is indicated in those horses with active conjunctivitis, keratitis, or uveitis attributable to onchocerciasis and includes antiinflammatory agents such as topical corticosteroids and systemic flunixin meglumine, topical echothiophate iodide 0.025%, and systemic diethylcarbamazine, levamisole, or ivermectin[3] (Table 15-2).

15.4.2 NEOPLASIA

Neoplasms affecting the conjunctiva and third eyelid include squamous cell carcinoma (SCC), lymphosarcoma, 999
melanocytoma, mastocytoma, hemangioma, and angiosarcoma.[3,23] Diagnosis and characterization of adnexal 1000
neoplasms is based on history, signalment, location, appearance, and histopathologic examination. One can perform routine surgical biopsy with sedation, local nerve blocks, and topical anesthesia. Most adnexal

neoplasms are benign or locally invasive, the exception being ocular angiosarcoma, which is reported to have a high incidence of metastasis.[24] Treatment of adnexal neoplasms varies according to tumor type, location, and size; use of the animal; treatment modalities available; and cost. The aim of treatment is to eliminate the tumor, restore normal anatomy, and maintain function of the eye and associated structures.

TABLE 15-2 Systemic Treatment of Ocular Onchocerciasis

DRUG	DOSE
Diethylcarbamazine	4.4–6.6 mg/kg/day orally for 21 days
Levamisole	1.1 mg/kg/day orally for 7 days
Ivermectin	0.2–0.5 mg/kg intramuscularly

SCC is the most common tumor of the equine eye and adnexa (Figure 15-2). Involvement can be unilateral or bilateral, with the third eyelid and medial canthus affected most frequently.[16,25] Involvement of the corneal limbus, sclera, conjunctiva, and other adnexal structures also has been reported.[16,25,26]

The mean age of onset for SCC is 9.8 years for all horses compared with 3.8 years for ocular sarcoidosis.[26] The incidence of ocular SCC is higher in draft-breed horses and Appaloosas than in light horses,[27,28] and sexually intact males and females have a decreased incidence.[27] Adnexal hypopigmentation and increased exposure to actinic radiation[26,27] are hypothesized to predispose horses to develop ocular SCC.

Figure 15-2 Squamous cell carcinoma affecting the temporal conjunctiva, limbus, and cornea.

Ocular SCC is malignant and locally invasive with the potential to metastasize.[22,29] Metastases to local and cranial mediastinal lymph nodes, parotid salivary glands, and the thoracic cavity occur in 10% to 15% of patients.[28]

Treatment of ocular SCC varies and must be designed for the individual patient. Surgical excision,[26] radiofrequency hyperthermia,[30] cryotherapy,[31] immunotherapy,[31] radiation therapy,[26,29–31] intralesional chemotherapy,[9,32] laser surgery,[7] or a combination of these,[30,31] have been used with success. Location, size, and depth of the tumor, visual status, financial commitment, purpose of the animal, and the presence or absence of metastatic disease influence the choice of therapy.

If possible, complete surgical excision is curative and is the preferred therapy. Difficulty arises with surgical excision when preservation of the globe and ocular and adnexal anatomy and function are required. Complete excision of the third eyelid is possible and often can be performed using sedation and local nerve blocks. To avoid possible herniation of the orbital fat, one should appose the bulbar and palpebral margins of the third eyelid conjunctiva following excision using 5–0 to 6–0 absorbable suture in a simple continuous pattern.

Most SCCs are radiosensitive and can be treated successfully with sources of β- or γ-radiation. The major disadvantage of less expensive modes of radiation therapy, such as strontium 90, a source of β-radiation, is the size limit of tumor amenable to treatment. With ^{90}Sr, for example, half the β-radiation produced is lost after passage through 1 mm of soft tissue. Thus one should limit treatment to lesions less than 2 mm deep, such as corneal, scleral, or conjunctival SCCs. Radiation is most appropriate as an adjunct therapy following surgical removal of a corneal or conjunctival SCC. When used appropriately, ^{90}Sr can achieve a nonrecurrence rate for SCC of 87.5% after 2 years.[33]

The use of interstitial radiotherapy for periocular SCC has been reported.[30,33] Radioactive gold seeds (^{198}Au) were used to impart a medium-energy γ-ray (0.41 MeV) with a half-life of 93.3 hours for a total recommended dose of 5000 rad.[30] Success rates of 80% at 1 year and 70% at 2 years are reported.[33] Disadvantages of radioactive implants are substantial cost, limited availability, risks associated with human exposure, and the licensing restrictions on their handling.[30] Secondary complications of interstitial radiation therapy include temporary corneal opacity, local necrosis, hair loss, damage to normal structures, and local depigmentation.[30,33] Although no retinal or lens changes have been reported following interstitial radiation treatment, one should consider the possibility of photoreceptor damage and cataractogenesis following radiation therapy.

Radiofrequency hyperthermia involves the passage of a radiofrequency (2 MHz) electric current between two 1000
electrodes. Tissue between these probes offers resistance, resulting in thermal energy being transferred to the 1001
tissue. Tissue temperature increases to 50° C in a 1-cm^2 area,[30] with malignant cells exhibiting a greater sensitivity to thermal energy than normal cells. One should not use topical radiofrequency hyperthermia as the only mode of treatment for tumors extending deeper than 3 mm or greater than 4 to 5 cm in diameter. Superficial eyelid SCCs or corneal and conjunctival SCCs are most appropriate for treatment using radiofrequency hyperthermia. One should avoid overlapping the fields of exposure, especially in corneal tumors, because this creates a risk of excessive necrosis of normal tissue.[34]

Cryosurgery using nitrous oxide (80°C) or liquid nitrogen (185°C) in a single freeze– or double freeze–thaw cycle results in tissue destruction. Cryodestruction is most often indicated for treatment of eyelid SCCs.

Associated local depigmentation of skin and hair may occur in the treated area. One should use thermocouples, and tissue temperatures of −25° C are optimal.

Intralesional chemotherapy with cisplatin or bleomycin in an oil-water emulsion has been reported to result in regression of equine SCC. Treatment is the same as previously described for eyelid sarcoidosis. Of those horses with adnexal SCC treated with intralesional cisplatin, 65% to 93% were relapse free at 1 year.[9,32]

Regardless of the treatment used, frequent and continued follow-up examinations result in the greatest long-term success in managing ocular and periocular SCC. Recurrence may happen at the initial site of involvement and must be distinguished from granulation tissue associated with the previous treatment. In addition, one must monitor other sites and the opposite eye for the development of new SCC lesions.

15.5 Nasolacrimal System

The nasolacrimal system consists of the superior and inferior puncta and canaliculi, nasolacrimal sac, nasolacrimal duct, and nasal punctum located on the floor of the nasal vestibule.[35] The nasolacrimal system serves to carry tears from the medial canthus of the eye to the nasal vestibule. Abnormalities of the nasolacrimal system result in epiphora, an overflow of tears, following an impairment in drainage of tears. Epiphora can be serous, mucoid, or mucopurulent and must be differentiated from reflex lacrimation resulting from ocular irritation or inflammation. Examination of the nasolacrimal system includes placement of fluorescein stain in the conjunctival cul-de-sac and observing its appearance at the nasal opening. One can irrigate the nasolacrimal system antegrade from the eyelid punctum or retrograde from the nasal punctum. One applies topical anesthetic (0.5% proparacaine) to the eye and places a 3.5F open-ended feline urinary catheter in the superior punctum. One uses sterile eyewash or saline (10 to 20 ml) to irrigate the system, first observing fluid passing out of the inferior punctum and subsequently, the nasal punctum. If one performs retrograde irrigation from the nasal punctum, one uses a 5F or 6F urinary catheter and increases the volume of irrigating solution. One can perform radiographic imaging of the nasolacrimal duct, dacryocystorhinography, using contrast material injected into the duct from the superior eyelid punctum.[3,35] Lateral and oblique radiographic views are best, and useful contrast materials include 60% barium sulfate (Novapaque, Picker Corp., Cleveland, Ohio) and 31% diatrizoate meglumine and diatrizoate sodium (Renovist II, Squibb Diagnostics). Indications for dacryocystorhinography include chronic epiphora, inability to irrigate the nasolacrimal duct, suspicion of a nasolacrimal foreign body, or evaluation of the nasolacrimal duct for congenital or acquired abnormalities.

Abnormalities of the nasolacrimal system can be congenital or acquired. In the horse the most common congenital abnormality is atresia of the distal portion of the nasolacrimal duct and the nasal punctum, which results in mucoid epiphora at 3 to 4 months of age.[3,36] Additional abnormalities include atresia of an eyelid punctum, abnormal placement of an eyelid punctum, and multiple nasal openings.[3,23] Whether these conditions are inherited is unknown. To correct an atretic nasal opening, one passes a catheter from the inferior eyelid punctum to the level of the atresia. One palpates the end of the cathete in the nasal vestibule and makes an incision through the nasal mucosa overlying the catheter, exposing the catheter. One then brings the tubing out the nasal opening and, along with the portion of tubing from the inferior punctum, sutures it to the skin of the face. One leaves the tubing in place for 3 to 4 weeks and administers topical broad-spectrum ophthalmic antibiotic solution during this time.

Acquired conditions of the nasolacrimal system include dacryocystitis, foreign body obstruction, trauma, and involvement secondarily in neoplastic or inflammatory conditions of the medial canthus. Dacryocystitis appears as a mucopurulent ocular discharge without associated ocular inflammation. Dacryocystitis and foreign body obstructions are treated by nasolacrimal irrigation, as previously described, and bacterial and fungal culture with

or without the aid of radiographic evaluation. One administers topical broad-spectrum ophthalmic antibiotic solution following irrigation. One also can use topical corticosteroids or systemic nonsteroidal antiinflammatory drugs (NSAIDs) to help control swelling and inflammation. Traumatic or other damage to the nasolacrimal duct is best repaired at the time of injury, and placement of a tube in the nasolacrimal duct for 3 to 4 weeks to maintain 1001
patency while healing occurs is recommended. Surgical repair of the nasolacrimal duct is a referral procedure and 1002
requires general anesthesia. If the nasolacrimal duct cannot be made patent, treatment is symptomatic therapy for the epiphora or surgical trephination (conjunctivorhinotomy) to create a new outflow pathway for the tears.

15.6 Cornea

15.6.1 ANATOMY AND PHYSIOLOGY

The cornea consists of the epithelium, stroma, Descemet's membrane, and endothelium. The epithelium is 7 to 15 cells thick and is replaced every 7 to 10 days. The corneal endothelium is a monolayer of cells with little to no regenerative capacity. Damage to the endothelium is therefore of great significance, for complete repair is often not possible and results in permanent corneal edema. The cornea is transparent and avascular and is supplied with sensory nerves from the ophthalmic branch of the trigeminal nerve. The epithelium and anterior stroma are innervated richly with sensory nerves, whereas the middle and inner cornea is less well supplied. Nutrition and waste removal are carried out by the tear film, aqueous humor, and diffusion to and from the scleral and conjunctival blood vessels. The cornea is maintained in a state of deturgescence by the mechanical barrier and pump mechanisms of the epithelium and endothelium. Interference with these barriers results in corneal edema, with endothelial damage being the more significant. Chronic irritation of the cornea results in superficial vascularization, whereas inflammation of the anterior uvea results in deep corneal vascularization. Corneal pigmentation often follows vascularization. Cellular infiltration of the cornea occurs in neoplastic, infectious, and inflammatory disease. All of these processes can occur alone or in combination, resulting in an alteration of corneal transparency. In addition, scar formation and noncellular infiltrates such as mineral and phospholipid deposits (corneal degeneration) alter corneal transparency. Establishing the cause of these changes and, if possible, eliminating the cause are essential.

15.6.2 ULCERATIVE DISEASES

Corneal ulceration is perhaps the most frustrating and potentially devastating disease of the equine eye. Of all species commonly treated in veterinary ophthalmology, the cornea of the horse is the slowest to heal, is the most likely to become infected, and has the poorest prognosis for outcome. In addition, the size and temperament of the animal makes frequent treatment difficult for owner and veterinarian. In most instances, corneal ulceration results from an initial trauma, but secondary infection is common, especially in those eyes treated with topical corticosteroids following ulceration.

15.6.2.1 Clinical Signs and Diagnosis

A corneal ulcer is a break in the corneal epithelium. Clinically, ulceration results in lacrimation, blepharospasm, photophobia, conjunctival hyperemia, corneal edema, and possibly miosis and aqueous flare. The diagnosis of a corneal ulcer is based on these clinical signs and fluorescein staining of the cornea. The underlying stroma retains the fluorescein stain and appears green. One should submit bacterial and fungal culture samples from all corneal ulcers in the horse and should obtain culture samples from the margin of the ulcer, before instilling any therapeutic or diagnostic agents in the eye. Once one obtains a culture samples

and has stained the cornea with fluorescein, one applies topical anesthetic and obtains a scraping from the ulcer for cytologic examination. One places the cells on a glass slide and stains them to examine them for bacteria, fungal hyphae, and cell type. Gram's and Giemsa stains work well for examination. The presence of gram-negative rods indicates the possibility of an infection with *Pseudomonas* sp. The presence of fungal hyphae is pathognomonic for mycotic keratitis, with *Aspergillus* spp. and *Fusarium* spp. being the most frequent corneal pathogens. Mixed bacterial and fungal infections are common.

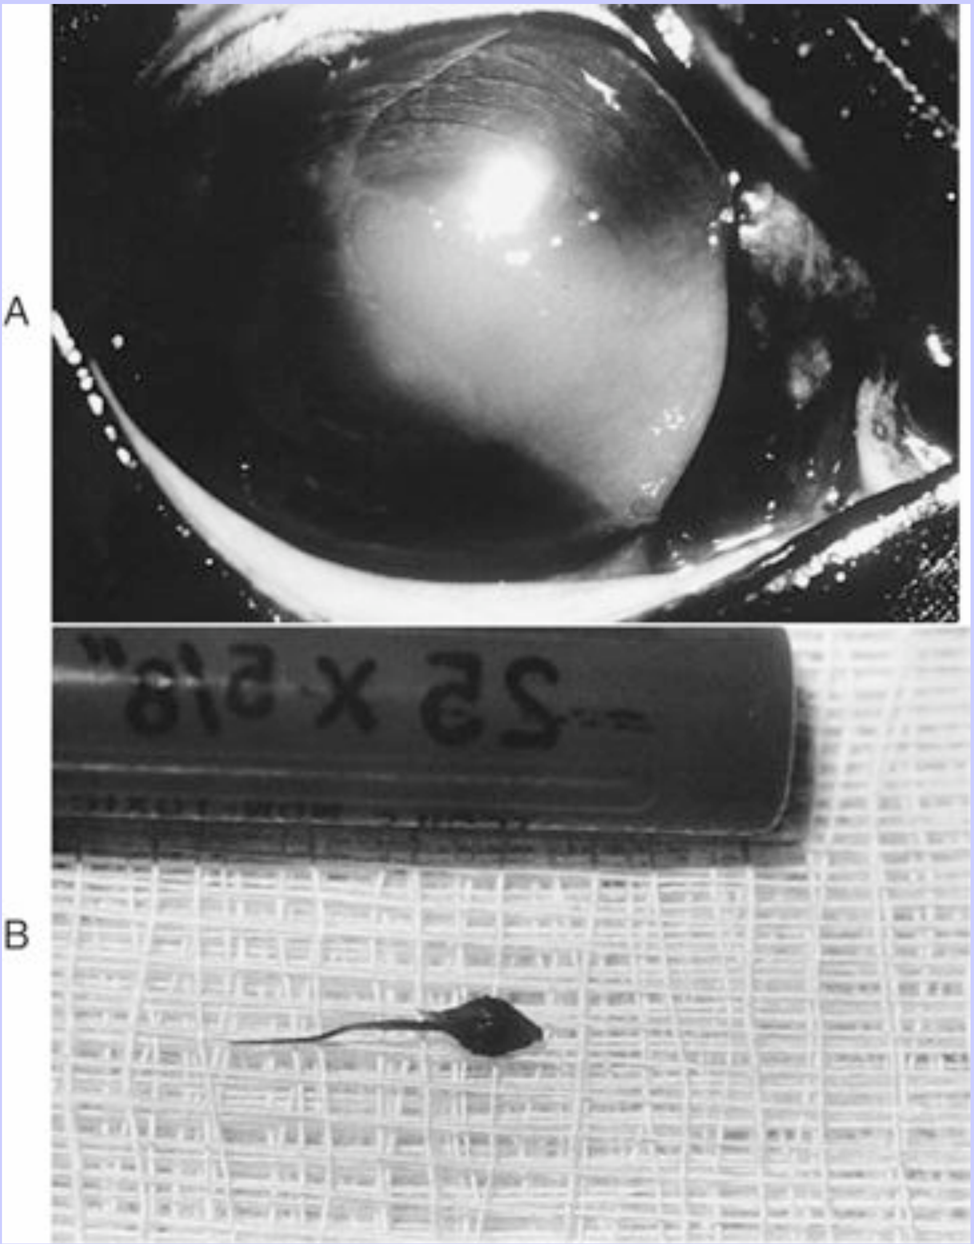
One should characterize a corneal ulcer according to size, depth, and the presence or absence of cellular infiltration. In addition, one examines the anterior chamber for anterior uveitis. With all corneal ulcers, one must attempt to establish the cause of the ulceration and eliminate it (Figure 15-3). One examines the palpebral conjunctiva and bulbar surface of the nictitans for the presence of a foreign body, evaluates the blink response and tear film, and obtains a complete history regarding trauma and previous medication. One must not administer topical corticosteroids in the presence of a corneal ulcer, and a history of previous topical corticosteroid therapy increases the likelihood of infectious, especially fungal, keratitis.

Some specific types of corneal ulcers in the horse include indolent ulcers,[37] ulcers with eosinophilic cellular infiltrate,[38] collagenase and mycotic ulcers, and possibly viral ulcerative keratitis.[3,23]

15.6.2.2 Routine Treatment

Treatment of an uncomplicated corneal ulcer involves controlling pain and inflammation, eliminating or preventing infection, and preventing secondary complications (Table 15-3). Healing occurs by migration and mitosis of the adjacent epithelial cells and depending on the size of the ulcer should be complete in 2 to 6 days for an uncomplicated corneal ulcer. Complicated corneal ulcers are those that fail to heal in an appropriate time, are secondarily infected, have an ongoing source of irritation or reulceration, have a 1002
collagenase component, are associated with corneal vascularization, or are worsening despite appropriate 1003
treatment.

Figure 15-3 **A,** Chronic, superficial corneal ulcer. The shape and orientation of the corneal ulcer suggest a foreign body on the bulbar surface of the nictitans. **B,** Foreign body removed after examination of the bulbar surface of the nictitans.



If one observes miosis, one can admininster topical atropine 1% to dilate the pupil, decrease the pain of anterior uveitis, and prevent posterior synechiae formation. One uses topical atropine as needed to dilate the pupil, but treatment frequency should not exceed 4 times daily. All topical ophthalmic medications are

absorbed and have systemic effects, and topical atropine can result in colic following ileus. During the time one administers topical atropine, one should evaluate intestinal motility by auscultation, and the owner should observe for fresh fecal material in the stall each day. Systemic flunixin meglumine is indicated to suppress inflammation and control pain associated with a corneal ulcer, which in combination with topical atropine helps dilate the pupil.

Topical broad-spectrum antibiotics such as neomycin-bacitracin-polymyxin B (Neosporin, Burroughs Wellcome Co., Triangle Park, North Carolina; AK-Spore, Akorn, Metairie, Louisiana) are the initial antibiotics of choice. Ointments are preferred for their ease of administration and prolonged corneal contact time. Frequency of administration varies according to severity of the disease. When one uses topical antibiotics prophylactically for an uncomplicated corneal ulcer treatment, administration 3 or 4 times daily is sufficient, but in severe infectious keratitis, therapy might be hourly. If one suspects infection with *Pseudomonas* sp., topical gentamicin, polymyxin B, tobramycin, or preferably ciprofloxacin is indicated every 2 to 4 hours. Although gram-positive organisms predominate initially in equine infectious keratitis, intensive topical antimicrobial therapy results in a significant shift to gram-negative organisms and a change in susceptibility patterns.[39] Additional treatment varies according to the type and severity of the ulcer (see Complicated Ulcerative Diseases).

One should not administer topical corticosteroids to a horse with a corneal ulcer.

15.6.3 COMPLICATED ULCERATIVE DISEASES

Complicated corneal ulcers are those that require treatment over and above routine ulcer management, are infected, exhibit chronicity or recurrence, are in imminent danger of perforation, or have a collagenase component (Figure 15-4). Secondary infection of a corneal ulcer is suggested by increasing corneal edema, interstitial keratitis associated with an increase in stromal inflammatory cells, corneal vascularization, purulent discharge, severe anterior uveitis, and stromal necrosis and liquefaction.

In many instances, complicated corneal ulcers require frequent and prolonged therapy, and some form of medication delivery system is indicated to ensure adequate treatment. Use of subpalpebral and nasolacrimal medication delivery systems has been described previously.[40] Placement of a through-and-through subpalpebral lavage system is described subsequently.

Many complicated corneal ulcers require a combination of surgical and medical therapy to improve the likelihood of a successful outcome.

15.6.3.1 Indolent Corneal Ulceration

Indolent corneal ulcers are by definition chronic and superficial.[37,41] Indolent ulcers often have a rim of loose or detached epithelium at the margin, focal corneal edema, moderate discomfort, and elicit minimal corneal vascularization. As with all chronic corneal ulceration, one must examine the eyelids, conjunctiva, and third eyelid thoroughly for the presence of foreign bodies, ectopic cilia, or other abnormality that might result in persistent ulceration.

The cause of indolent ulcers is suspected to be a failure in the attachment of the corneal epithelium to the 1003
underlying basement membrane. This attachment normally develops following epithelial migration and 1004
mitosis in the repair of a corneal ulcer. A basement membrane abnormality is suspected to be the underlying problem.

TABLE 15-3 Commonly Used Ophthalmic Medications

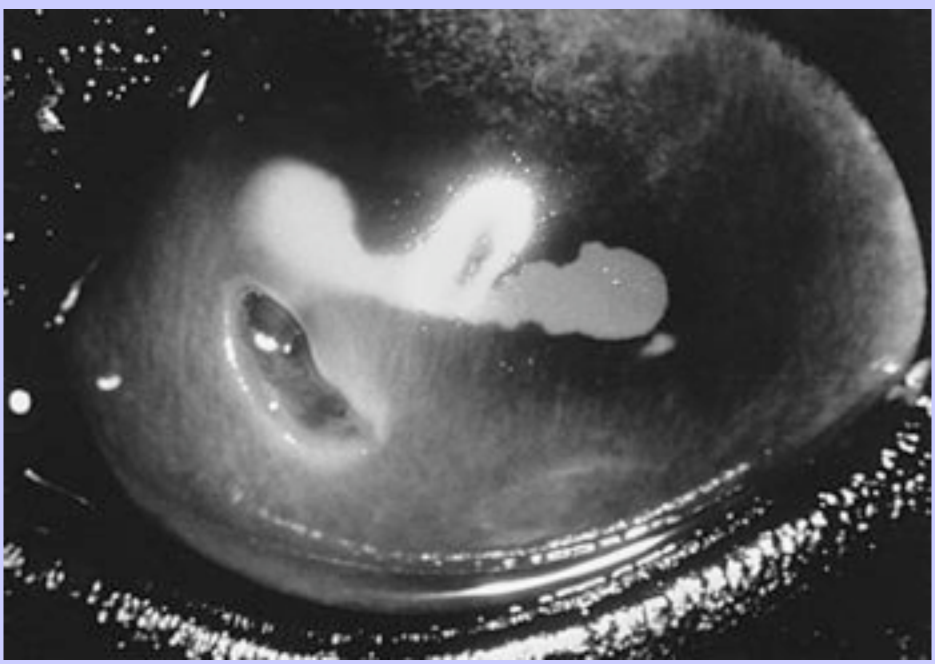
ROUTE TOPICAL	CATEGORY		DRUG	INDICATION	DOSE[*]
	Antibiotics		Gentamicin	Corneal ulceration	q2–6h
			Neomycin-bacitracin-polymyxin B	Corneal ulceration	q2–6h
			Tobramycin 0.3% (Tobrex)	Corneal ulceration	q2–6h
	Antifungals		Natamycin (Natacyn)	Corneal ulceration with suspected fungal keratitis	q2–4h
			Miconazole 1% IV, topical	Corneal ulceration with suspected fungal keratitis	q2–4h
	Antiinflammatories				
		Corticosteroids	1.0% Prednisolone acetate (Econopred Plus)		1–6/day
			0.1% Dexamethasone solution (Decadron)		1–6/day
			0.05% Dexamethasone ointment (Decadron)		1–6/day
		Nonsteroidal	0.03% Flurbiprofen (Ocufen)		4/day
			1.0% Suprofen (Profenal)		4/day
	Parsympatholytics		Tropicamide 1%	Diagnostic agent to dilate the pupil	Single dose
			Atropine 1%	Therapeutic agent to dilate the pupil long term	1–4/day
SUBCONJUNCTIVAL	(Do not exceed a volume of 1.0 ml)				
	Antiinflammatories				

	Corticosteroids	Dexamethasone acetate		10–15 mg
		Betamethasone		5–15 mg
SYSTEMIC				
	Antiinflammatories	Flunixin meglumine	Extra-or intraocular inflammation	1.1 mg/kg PO, IM, IV b.i.d.
		Phenylbutazone	Extra-or intraocular inflammation	2–4 mg/kg PO b.i.d.
		Aspirin	Extra-or intraocular inflammation	25 mg/kg PO, IV s.i.d/b.i.d.

* *PO,* Orally; *IM,* intramuscularly; *IV,* intravenously.

Treatment of indolent corneal ulcers includes removal of abnormal, loose epithelium and facilitation of epithelial attachment. Following sedation, auriculopalpebral nerve block, and topical anesthesia, one debrides the loose epithelial margins of the indolent ulcer to the point of normal attachment using a cotton swab or cilia forceps. One then performs a superficial linear keratotomy using a 25-gauge needle. Using the beveled edge of the needle, one places a series of superficial, parallel horizontal and vertical grooves in the cornea 0.5 to 1.0 mm apart that extend through the basement membrane and need be only deep enough to be visualized.

Figure 15-4 Deep corneal ulcer and descemetocele with associated focal corneal edema and miosis.



These areas serve as attachment sites for the migrating epithelium, shortening the healing time. One administers topical, broad-spectrum antibiotics every 6 hours and, if miosis is present, uses atropine 1% as needed to dilate the pupil. Systemic NSAIDs improve patient comfort. Use of a soft contact lens, 24 to 36 mm in diameter (OpTECH, Inc., Englewood, Colorado), may help protect the corneal epithelium from the shearing forces of the eyelid and third eyelid during healing but is not essential. Topical hyperosmotics have been advocated for indolent corneal ulceration but are of no benefit in the author's opinion, and topical corticosteroids are contraindicated. One can use a superficial keratectomy or a conjunctival pedicle graft or both for indolent ulcers that fail to respond to debridement and superficial linear keratotomy. 1005

15.6.3.2 Superficial Punctate Keratitis

Superficial punctate keratitis is characterized by multifocal, lacelike epithelial to subepithelial corneal opacities, some of which may be flourescein-positive, with mild corneal edema. Blepharospasm may be evident, but many horses are asymptomatic. The cause is unknown, but viral agents, specifically equine herpesvirus type 1, onchocerciasis, and immune-mediated causes have been proposed.[13,44,45]

Treatment recommendations vary and include topical antibiotic and corticosteroid application 3 to 4 times daily, topical cyclosporin A,[46] topical antiviral therapy, or a combination of these. Although the condition may respond to topical corticosteroids, recurrence is common, and one must exercise extreme caution when using topical corticosteroids. Topical ophthalmic antiviral agents (idoxuridine and trifluridine) or cyclosporin are administered every 6 to 8 hours and are the treatment of choice for most ophthalmologists.

15.6.3.3 Eosinophilic Keratoconjunctivitis

Eosinophilic keratitis may present with blepharospasm, chemosis, and conjunctivitis, but the hallmark feature is a yellow-white caseous plaque adhering to the limbal cornea with perilesional edema and corneal ulceration.[38,47] One also may find similar caseous material adhering to areas of ulcerated conjunctiva. Cytologically, the caseous material is predominantly eosinophils with a few mast cells.[38] The lesion may be unilateral or bilateral, and more than one lesion may be present within an eye. The condition appears seasonally, presenting in the spring and summer. The diagnosis is based on clinical signs, season of the year, and cytologic examination.

Untreated, eosinophilic keratoconjunctivitis is a chronic disease with healing by vascularization and scarring over several months. During this time secondary infection and acute exacerbation is possible. Treatment with topical corticosteroids has been described as reducing clinical signs, but mean time to resolution was 64 days, which is not significantly greater than without treatment.[38] In addition, secondary bacterial or fungal infectious keratitis is a risk with the use of topical corticosteroids. Topical lodoxamide 0.1% (Alomide, Alcon Laboratories) every 6 to 8 hours is the treatment of choice, along with fly control using fly masks. Superficial keratectomy also may be of benefit in resolving eosinophilic keratoconjunctivitis.

15.6.3.4 Mycotic Keratitis

One must consider all chronic corneal ulcers and ulcers that have been treated with topical corticosteroids as mycotic ulcers until proved otherwise. Keratomycosis is more common in the summer months and in warm climates.[48] Mycotic ulcers often have multifocal areas of cellular infiltrate and colonies of fungal organisms

(Figure 15-5) that appear as white lesions deep in the corneal stroma adjacent to the ulcer and often appear 7 to 10 days following initial ulceration. These infiltrates are often fluorescein-negative. Diagnosis of mycotic keratitis is based on history, clinical signs, cytologic examination, culture, and if possible, histopathologic examination of a biopsy sample (Figure 15-6). Failure to see fungal elements on cytologic examination or culture does not rule out mycotic keratitis. The most common isolate for eyes with keratomycosis is *Aspergillus* sp.[48] *Fusarium* spp., *Penicillium* spp., and *Candida albicans* also are associated with keratomycosis. If in doubt, treating the horse for fungal infection is appropriate.

In eyes in which mycotic keratitis is suspected or documented, topical antifungals are indicated in addition to routine ulcer management. The only approved ophthalmic antifungal is natamycin 5% suspension (Natacyn, Alcon Laboratories), but it is often cost-prohibitive. Although not approved for ophthalmic use, the 1005
imidazole antibiotics (miconazole, ketoconazole) may have the best efficacy for the treatment of 1006
keratomycosis.[48] Miconazole 1% can be compounded as a solution or ointment and administered every 2 to 4 hours topically for mycotic keratitis. An itraconazole–dimethyl sulfoxide ointment also has been used topically to treat keratomycosis.[49] In addition, dilute povidone-iodine solution is fungicidal and can be applied to the cornea with a cotton swab once every 1 to 2 days. Iodine is irritating to corneal and conjunctival tissues and should be irrigated from the conjunctival cul-de-sac following application. All topical antifungal medications have limited ability to penetrate intact corneal epithelium, although miconazole is better than most. If the lesion is fluorescein-negative, debriding the epithelium before medicating may be necessary (see Corneal Stromal Abscess). One must continue administering topical antifungal medication for a minimum of 3 to 4 weeks along with concurrent routine topical and systemic corneal ulcer management. Dermal antifungal preparations are not appropriate for topical use in the eye, but one may administer human vaginal antifungal preparations as a last resort.

Figure 15-5 Mycotic keratitis. Deep corneal vascularization, stromal edema, and cellular infiltration resulted from infection with *Aspergillus* sp.

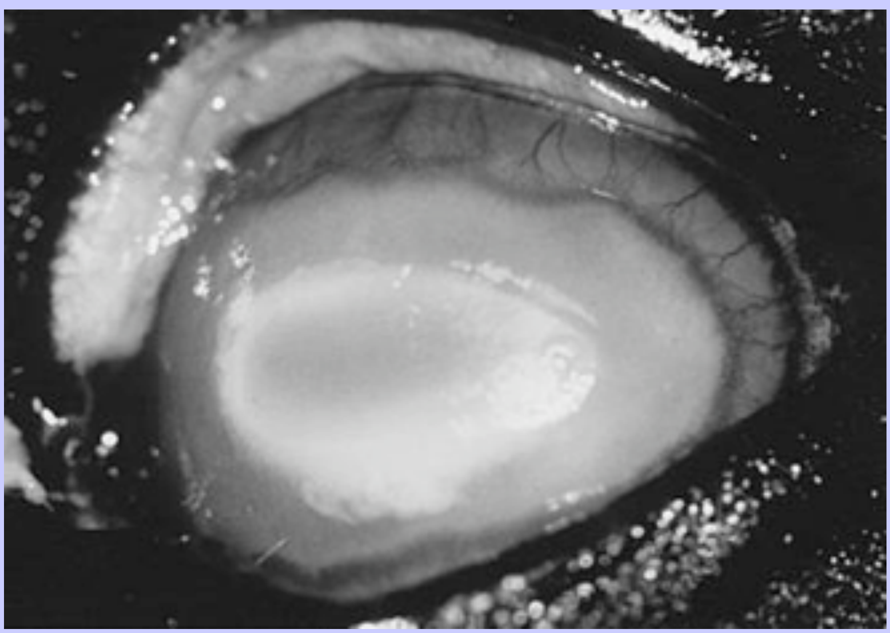


Figure 15-6 Corneal cytologic sample from horse with a combined infection of *Aspergillus* sp. and *Streptococcus* sp. Filamentous hyphae and bacteria are present in the sample.

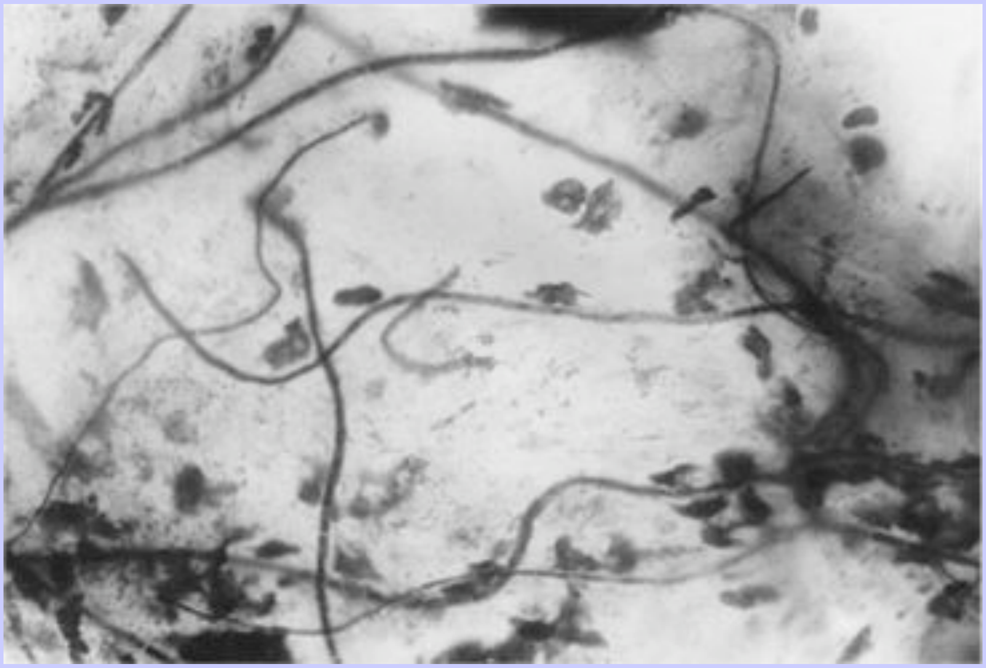


Recently, use of the systemic antimycotic agent fluconazole has been evaluated.[50] In the author's opinion, oral administration of fluconazole (Diflucan, Pfizer Roerig, New York) at 1 mg/kg every 12 hours for 14 days and then every 24 hours for 7 days is associated with significant improvement and resolution of early keratomycosis and corneal stromal abscessation following fungal infection.

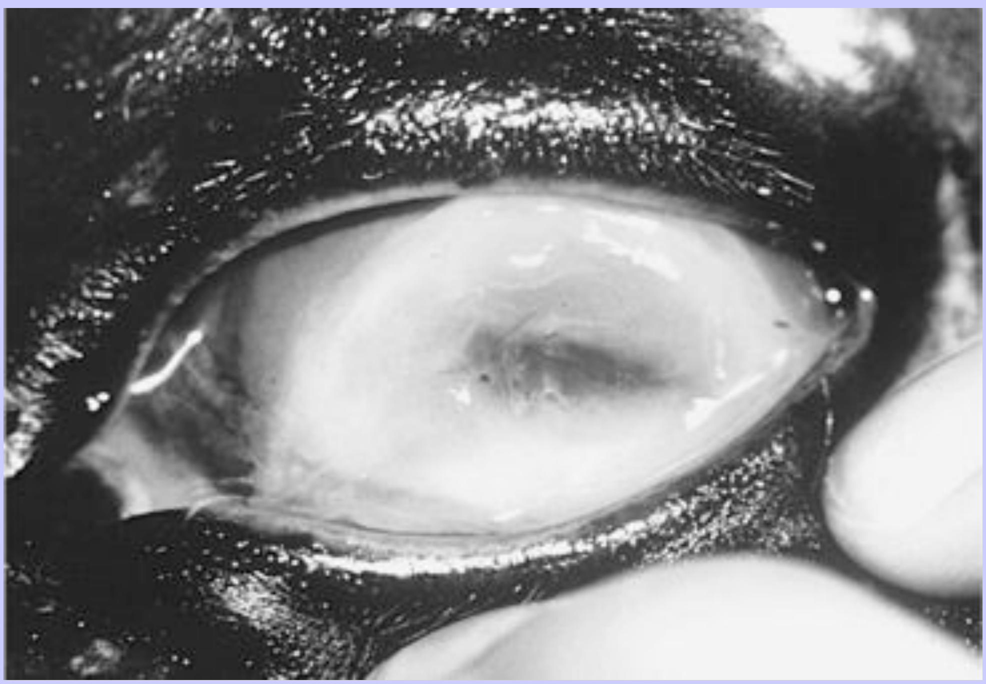
Many mycotic corneal ulcers are managed best using a combination of surgical and medical management.[23] Surgical debridement in the form of a partial or full-thickness keratectomy may help to remove much or all of the infected corneal stroma, respectively; is performed under general anesthesia; and requires microsurgical instrumentation and magnification. For a partial-thickness keratectomy, one may manage the resulting ulcer medically or, more appropriately, may suture a conjunctival pedicle graft[3,51,52] to the ulcer to aid in healing. The corneal vascularization provided by a conjunctival graft facilitates healing. One can perform a penetrating keratoplasty with a corneal transplant for deeper lesions[53] (see Corneal Surgery). Most mycotic corneal ulcers/abscesses ultimately vascularize and scar to some degree regardless of the treatment method. Topical corticosteroids have little if any effect on corneal scar formation and are not indicated, even following resolution of keratomycosis, because the possibility of sequestered organisms exists with subsequent exacerbation.

15.6.3.5

Collagenase Ulcers

Keratomalacia, or corneal melting, results from host-derived collagenase (from neutrophils and keratocytes) and bacterial enzymes such as those produced by *Pseudomonas aeruginosa*.[54] Collagenase ulcers progress rapidly and can result in corneal perforation within 24 hours (Figure 15-7). One should obtain samples for bacterial and fungal culture and cytologic examination. Cytologic examination must include Gram's staining to examine for the presence of gram-negative rods suggesting *Pseudomonas* spp. The topical antibiotics of choice for *Pseudomonas* are tobramycin 0.3% or ciprofloxacin (Ciloxan, Alcon Laboratories)[39,54] every 2 hours. One can administer a topical anticollagenase such as acetylcysteine (Mucomyst, Mead Johnson Pharmaceutical, Evansville, Indiana) diluted to a 5% to 8% solution with artificial tears or autologous serum
every 4 hours to minimize collagenase activity. Topical tetracycline every 4 to 6 hours also may be of benefit 1006
because it inhibits metalloproteinases that are activated in keratomalacia. In addition, debridement and a 1007
conjunctival pedicle graft or penetrating keratoplasty often are indicated to repair the defect, aid in healing, and prevent corneal perforation.

Figure 15-7 Severe melting caused by collagenase ulcer following infection with *Pseudomonas aeruginosa*. Corneal malacia surrounds a large descemetocele.



15.6.3.6

Descemetocele

Descemet's membrane is the basement membrane of the endothelium and the last barrier to corneal perforation. Descemet's membrane does not stain with fluorescein and appears as a clearing in the center of an otherwise edematous corneal ulcer (see Figure 15-4). As with all corneal ulcers in the horse, routine

diagnostic procedures for a descemetocele include culture and cytologic examination. A descemetocele is a surgical emergency and likely requires referral to a veterinary ophthalmologist. Surgical management is designed to provide support to the weakened cornea and blood vessels and fibroblasts to repair the damage. Support is achieved with a conjunctival graft or a lamellar or penetrating keratoplasty (see Corneal Surgery). Routine treatment for a corneal ulcer follows surgery and is best delivered through a subpalpebral lavage system to avoid manipulation of the eyelids and corneal graft. The conjunctival graft may be debrided 6 to 8 weeks after surgery in an attempt to minimize scar formation by severing the blood supply to the graft tissue.

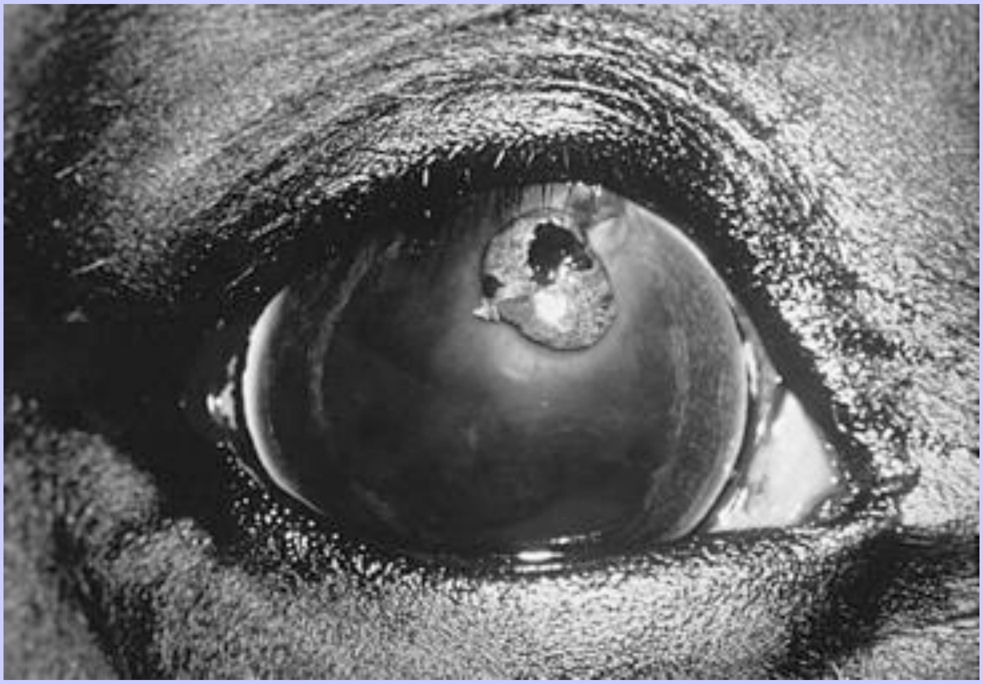
15.6.3.7

Corneal Perforation and Laceration

Causes of corneal perforation include rupture of a deep corneal ulcer or descemetocele and sharp and blunt trauma. Depending on the cause of the perforation and severity of the damage, treatment involves primary repair, an intraocular prosthesis, or enucleation. If the horse is to be referred for consultation and treatment, one can prevent self-trauma during transportation by using cradles or other protective devices and sedation as required. The prognosis following a penetrating injury varies depending on the cause, size of the wound, location, depth of penetration, intraocular damage, and the presence or absence of infection or retained foreign objects. In general, perforating corneal wounds in the horse have a grave prognosis for vision and a guarded prognosis for cosmesis. Such wounds always are associated with secondary anterior uveitis, and an iris prolapse is usually present (Figure 15-8). Sequelae to a corneal perforation include corneal scar, anterior and posterior synechiae, cataract, glaucoma, retinal detachment, phthisis bulbi, blindness, and loss of the eye.

Primary repair of a corneal perforation is a referral procedure. Treatment includes repairing the rent, reestablishing the anterior chamber, preventing infection, and decreasing inflammation and pain. Removal of a penetrating object is best done at the time of repair. One administers tetanus toxoid before repair. One should culture the aqueous humor, along with any retained foreign objects, for aerobic bacteria and fungi. If iris tissue protrudes but appears viable and minimally contaminated, one replaces it; however, one amputates contaminated, nonviable iris using electrocautery to minimize hemorrhage. If electrocautery is not available, one can perform sharp excision and control the bleeding. Intracamerally administered epinephrine, 1:10,000, can help control intraoperative bleeding and also facilitates pupil dilation. One can use a viscoelastic agent to tamponade vessels in addition to maintaining the anterior chamber and manipulating tissues. If the lens capsule has ruptured secondary to trauma, one should remove the lens; lens protein is antigenic and may stimulate severe anterior uveitis. If one can appose wound margins, one repairs the cornea with partial-thickness, simple interrupted or continuous 7–0 to 8–0 absorbable sutures. One reforms the anterior chamber with a balanced salt solution or, if unavailable, lactated Ringer's solution. One can use conjunctival grafts to promote rapid corneal healing and vascularization and to provide support. If a portion of cornea is missing or the wound edges cannot be apposed, a corneal-scleral transposition or other type of graft procedure is required. Following surgery, one administers topical broad-spectrum antibiotics every 2 to 4 hours, uses topical atropine as needed, and administers systemic antibiotics and flunixin meglumine. Use of a subpalpebral lavage delivery system is indicated.

Figure 15-8 Corneal perforation with associated hyphema and iris prolapse.



Blunt trauma, whether contusive, penetrating, or perforating, generally results in more severe ocular damage than injury from a sharp object[5] (Figure 15-9). In contrast to sharp perforating injuries, blunt trauma results in a rapid increase in IOP, an explosive rupture from the inside outward, and the expulsion of the intraocular 1007
contents. The resulting rent in the fibrous tunic is often large and irregular, and portions of the cornea or 1008
sclera may be lost. The typical wound is one that originates at the limbus, extending forward into the cornea and posterior into the sclera. If the posterior portion of the eye ruptures, the horse may show hyphema and decreased IOP and may require ocular ultrasound for accurate diagnosis.

Figure 15-9 Corneal perforation following blunt trauma. The lesion is explosive and expulsive with loss of intraocular contents. Enucleation is the treatment of choice.

Repair of these explosive ruptures is difficult, and the treatment of choice may be enucleation. If cosmetic repair is important, one may use an intraocular silicone prosthesis in some patients, provided enough tissue is left to close the fibrous tunic.[3] One should perform this procedure as soon as possible following injury. If the injury is chronic and atrophy of the globe has occurred, placement of an intraocular prosthesis is not possible. The only cosmetic alternative in these horses is an orbital prosthesis, which is expensive, time-consuming, and requires frequent maintenance on the part of the owner.[3]

15.6.4 TECHNIQUE FOR PLACEMENT OF A SUBPALPEBRAL LAVAGE DELIVERY SYSTEM

A subpalpebral lavage delivery system works well to facilitate administration of topical medication in a horse with ocular pain or a fractious temperament. One can place the system using sedation, auriculopalpebral and supraorbital nerve blocks, topical anesthesia, and appropriate equipment (Box 15-2). The through-and-through subpalpebral lavage technique described is preferred over other subpalpebral lavage or nasolacrimal delivery systems.[40] This technique results in less irritation and fewer complications, and the system is less likely to become displaced. Recently, a technique for inferomedial placement of a single-entry subpalpebral lavage tube has been described.[55]

15.6.4.1

BOX 15-2 EQUIPMENT REQUIRED FOR PLACEMENT OF A SUBPALPEBRAL LAVAGE DELIVERY SYSTEM

Sedation

- Xylazine, 100 mg/ml
- Butorphenol, 10 mg/ml

Nerve blocks

- Carbocaine 2%
- 25-guage needle

Topical anesthetic

- Proparacaine 1%

Hubless 12-guage needle

Silastic tubing (0.065-mm outer diameter)

1-inch tape

2–0 Vetafil suture

Tom cat urinary catheter, open ended

Sterile injection cap

Tongue depressor

From Wilkie DA: Ophthalmic procedures and surgery in the standing horse, *Vet Clin North Am Equine Pract* 7:535-547, 1991.

Once one sedates the horse and performs the nerve blocks, one elevates the superior eyelid and directs a 12-gauge hubless needle superotemporally from the conjunctival surface. One must take care to avoid traumatizing the cornea and always must direct the needle from the conjunctiva out to skin to minimize the possibility of ocular trauma. One places the needle as far temporal and into the conjunctival fornix as possible while remaining anterior to the bony orbital rim. One then passes the needle through the superior eyelid and out the skin and passes the Silastic lavage tubing through the needle and removes the needle. Silastic tubing is preferred because of its low tissue reaction and pliability. One then repeats the procedure in the superonasal portion of the eyelid, again directing the needle outward from the conjunctiva and as far from the temporal hole as possible. One must perform the technique with a hubless needle to allow both needle passes to be directed away from the eye. One then passes the tubing through the needle and removes the needle. One ties a knot in

the medial portion of the tubing as it emerges from the skin of the superior eyelid, places enough throws so that the tube does not migrate back through the eyelid, and makes the throws tight enough to occlude the lumen.

One approximates the amount of tubing on the inside of the eyelid adjacent to the palpebral conjunctiva. One pulls the tubing nasally and makes two or three small holes in that portion of the tubing midway between the 1008
two eyelid puncture wounds, taking care to avoid severing the tube. One then pulls the tube back into place. 1009

One sutures the tubing to the skin of the lateral canthus and to the forehead to prevent migration of the tubing. One can attach the tube to the halter or, in those animals that are extremely difficult to medicate, to the mane on the affected side. One inserts an open-ended feline urinary catheter in the end of the Silastic tubing and attaches an injection cap, which one then tapes to a tongue depressor to provide support, and one attaches the entire apparatus to the halter, taking care to avoid kinking the tubing. One then should test the system using sterile eyewash. One observes the irrigating solution dripping over the cornea and running down the face to be certain tube placement is correct. One also takes note of the volume of solution required to reach the eye. This indicates the volume of air required to deliver the medication to the eye.

Medication used with a subpalpebral lavage system must be in solution, not ointment. The volume of medication used at each treatment time should be 0.1 ml, and one then must use air to deliver this medication to the eye. The use of irrigating solution to deliver the medication dilutes the medication. One should not exceed 0.1 ml because this medication will be absorbed systemically and excessive volume simply overflows onto the face. A 25-gauge needle works well for injecting medication and preserving the injection cap. Once daily one should irrigate the system with sterile eyewash to ensure its patency and to rinse away mucous buildup.

Complications from a subpalpebral lavage system include trauma during tube placement, improper placement of the delivery holes, irritation to the cornea from the tubing, and migration of the tubing. Observation of the medication reaching the cornea always is essential. Improper placement or migration of the tube may result in delivery of medication to the subcutaneous tissues and severe irritation. If corneal trauma occurs, one must remove the tube and replace it or find an alternative means of medication.

15.6.5 CORNEAL SURGERY

Surgery in the form of a superficial keratectomy, conjunctival graft, or corneal graft may be indicated in addition to aggressive medical therapy for many complicated corneal ulcers.[56] One must perform corneal surgery using general anesthesia to optimize the outcome.

A superficial keratectomy provides a biopsy for histopathologic examination, debrides and debulks damaged and infected corneal stroma, and provides a bed for transplanting and suturing a conjunctival or corneal graft. One uses a No. 64 Beaver blade or Martinez corneal dissector first to outline the area to be excised and then to undermine and remove the affected area of cornea. In general, one can remove 50% to 70% of the corneal thickness, but excision of 50% or more is an indication to reinforce the remaining cornea with a conjunctival or corneal lamellar graft. The normal equine cornea is 1.0 to 1.5 mm thick and is thinnest centrally. The cornea increases in thickness with disease because of edema, cellular infiltration, vascularization, and scar formation.

Conjunctival grafts include advancement, hood, bridge, pedicle, and complete conjunctival grafts.[51,52,56] The author prefers to perform a conjunctival pedicle graft for most focal corneal ulcers and uses the other types for more extensive lesions.[52] Before placement of a conjunctival graft, debridement of the affected cornea by superficial keratectomy is indicated. One mobilizes the bulbar conjunctiva, leaving an intact blood supply. One should attempt to appose conjunctival and corneal epithelium at the edge of the graft and to place 7–0 to 8–0

Vicryl (polyglactin 910) sutures two thirds deep into healthy cornea. A continuous suture pattern, simple or double, works best and is associated with less graft retraction and dehiscence than a simple interrupted suture pattern for equine conjunctival grafts. Conjunctival grafts adhere to the underlying exposed corneal stroma, providing the blood supply and cells required to repair and rebuild the damaged cornea. Opacification of the graft site occurs but is generally less than what would have occurred without surgery. One can minimize opacification by trimming the graft and severing its blood supply 6 to 8 weeks following the initial surgery.

Autologous and homologous lamellar corneal grafts, corneal-scleral transposition, and penetrating keratoplasty are more involved techniques reserved for the most severe corneal ulcers or for perforating corneal lesions. These are described elsewhere and are referral procedures.[56]

Nictitating membrane or third eyelid flaps are of little or no benefit for managing complicated and infected equine corneal disease and are contraindicated in many instances.

15.6.6 NONULCERATIVE DISEASES

Nonulcerative corneal diseases include corneal scar, corneal edema, stromal abscessation, cellular and noncellular infiltrates, and nonulcerative keratouveitis.[57]

Corneal scars are not painful, follow a history of corneal disease, and are associated with corneal vascularization. Topical corticosteroid therapy does not decrease corneal scarring significantly but does predispose the eye to infection and decreases healing in the event of a corneal ulcer. Tattooing of a corneal scar for ocular cosmesis is described[3,44] but not advised.

Cellular infiltration in the corneal stroma includes neoplastic and inflammatory cells. The most common 1009
corneal neoplasia is SCC (see Conjunctiva and Third Eyelid; Figure 15-2). Corneal lymphosarcoma also occurs. 1010
Inflammatory cellular infiltration (neutrophils, lymphocytes, plasma cells, eosinophils) occurs in infectious keratitis (bacterial, mycotic) usually and is associated with corneal ulceration. However, a small, focal corneal ulcer can become infected and reepithelialize, resulting in a corneal stromal abscess. In addition, inflammatory corneal infiltration occurs with equine ocular onchocerciasis and nonulcerative keratouveitis.

Noncellular corneal infiltration or corneal degeneration is a sequela of previous corneal or limbal inflammation. Accumulations of mineral and phospholipids may remain within the corneal stroma following inflammation and appear as crystalline infiltration. Such accumulations are rare, generally are not painful, and do not require treatment. In some instances, they predispose the eye to corneal ulceration and can be removed with a superficial keratectomy.[3]

15.6.6.1 Corneal Edema

Corneal edema, if not associated with a corneal ulcer (fluorescein-negative), results from corneal endothelial damage. Blunt trauma to the globe can result in displacement of the corneal endothelium from the posterior surface of the cornea, which results in full-thickness, diffuse corneal edema and which may gravitate to the ventral cornea with time. In addition, diseases of the anterior uvea and aqueous humor, anterior uveitis and glaucoma, and anterior lens luxation can interfere with endothelial cell function, resulting in diffuse corneal edema. Although no specific treatment exists for corneal edema of endothelial origin, hyperosmotic agents such as sodium chloride 5% (Muro-128, Bausch & Lomb, Rochester, New York) applied topically every 4 to 6 hours may decrease the severity of the edema and help prevent rupture of corneal bullae. In the author's

opinion, this has only minimal efficacy. With time, the corneal endothelium may reattach or adjacent endothelial cells may hypertrophy, resulting in a decrease in corneal edema. During the period that the edema is present, the cornea is compromised and at risk of ulceration. One therefore should avoid topical corticosteroids.

15.6.6.2 Nonulcerative Keratouveitis

A condition consisting of interstitial keratitis with peripheral corneal vascularization, edema, and cellular infiltrate and anterior uveitis (miosis, aqueous flare, iritis) has been described in five horses.[57] The pathogenesis of nonulcerative keratouveitis is unknown, but anterior uveitis has been suggested to follow interstitial keratitis and that an immune-mediated mechanism is involved. No infectious or neoplastic process is apparent. Histologically, nonulcerative keratouveitis is characterized by vascularization, fibroblasts, and inflammatory cells, predominantly lymphocytes. No infectious agents are visible on light or transmission electron microscopy.

Treatment is similar to that for equine recurrent uveitis and involves suppression of inflammation and control of ocular pain. Topical and subconjunctival corticosteroids, topical NSAIDs, topical cyclosporin A,[46] topical mydriatic cycloplegics, and systemic NSAIDs effectively control the signs, but some level of long-term maintenance therapy usually is required.

The differential diagnoses for nonulcerative keratouveitis include corneal stromal abscess, equine ocular onchocerciasis, and neoplasia.

15.6.6.3 Corneal Stromal Abscess

The usual cause of corneal stromal abscess formation is a focal, superficial corneal ulcer that allows opportunistic infection of the corneal stroma and then heals, trapping the microorganism. Topical antibiotic-corticosteroid therapy in eyes with corneal epithelial cell loss may predispose to stromal abscess formation.[3,58,59] The lesion results in discomfort apparent as photophobia, blepharospasm, and excessive lacrimation. A chronic, yellow-white, corneal stromal infiltrate with associated corneal edema and deep corneal vascularization is present.[58,59] Anterior uveitis may be present. Fluorescein staining of the cornea is often negative. Diagnosis is based on clinical signs. One should obtain a corneal scraping from the lesion, following removal of the overlying corneal epithelium, and should be submitted for cytologic examination, bacterial culture and sensitivity, and fungal culture. Gram-positive cocci (*Streptococcus* and *Staphylococcus* spp.) are the predominant organisms recovered,[58] but fungal stromal abscesses also occur. Differential diagnosis includes nonulcerative keratouveitis.

If the overlying epithelium is intact, one should remove it before initiating treatment to facilitate penetration of antibiotics. Ciprofloxacin is the topical antibiotic of choice because it penetrates intact corneal epithelium; its use is recommended every 4 hours pending culture and sensitivity results. In addition, some authors recommend subconjunctival injections of antibiotics.[3,58] If one suspects a mycotic stromal abscess, oral administration of fluconazole (Diflucan, Pfizer Roerig, New York) at 1 mg/kg every 12 hours for 14 days and then every 24 hours for 7 days is indicated.[50] Alternately, one can use an itraconazole-dimethyl sulfoxide ointment topically, but this may be associated with significant irritation.[49]

If anterior uveitis is present, one administers topical atropine 1% as needed to dilate the pupil, up to a maximum of 4 times a day. Systemic flunixin meglumine helps reduce ocular pain and secondary complications associated with inflammation. Topical corticosteroids are contraindicated. Resolution of the 1010
abscess requires 2 to 8 weeks, is associated with corneal vascularization, and results in corneal scar 1011
formation. In addition, the associated anterior uveitis may result in secondary intraocular complications.

A superficial keratectomy and conjunctival pedicle graft,[59] posterior lamellar keratoplasty,[60] or penetrating keratoplasty[53,61] is also appropriate and may result in a more rapid resolution and reduced corneal opacification than medical management alone. If one performs a keratectomy, one should submit the excised corneal stroma for culture and cytologic or histopathologic examination, for testing of the corneal stoma is more diagnostic than preoperative samples.[59]

15.6.6.4 Equine Ocular Onchocerciasis

Onchcocerca cervicalis is a common equine parasite and has been implicated in conjunctivitis, peripheral keratitis, anterior uveitis, and peripapillary chorioretinitis. Corneal lesions result from *Onchcocerca* microfilariae that migrate to and die in the corneal stroma and that may incite an inflammatory response. The lesion begins peripherally at the temporal limbus but can extend axially. Interstitial keratitis, manifested as corneal edema, vascularization, and subepithelial focal corneal opacities, occurs and may be associated with temporal bulbar conjunctival vitiligo, conjunctivitis, and anterior uveitis. Diagnosis is based on history, clinical signs, and the presence of eosinophils on cytologic examination and microfilariae on conjunctival biopsy.[62] One can demonstrate microfilariae cytologically through a biopsy of temporal bulbar conjunctiva, placing the sample on a slide with warm saline and examining for the presence of motile microfilariae. One must interpret the presence of microfilariae along with the clinical signs because one can find microfilariae in many horses without associated ocular disease.

Treatment includes suppression of ocular inflammation and microfilaricidal therapy (see Table 15-2). Topical corticosteroids and systemic phenylbutazone or flunixin meglumine control inflammation (see Table 15-3). If anterior uveitis is present, one can use topical atropine 1% as needed to dilate the pupil. Pretreatment with antiinflammatory medications for 2 to 3 days before administration of microfilaricides is indicated to minimize the ocular response to the dying microfilaria.

15.6.6.5 Band Keratopathy

Single or multiple linear streaks affecting one or both eyes in the horse have been described.[63] Histologically, these are areas of thinning of Descemet's membrane and may be congenital. The principle differential is a corneal stria following chronic glaucoma and enlargement of the globe with stretching of Descemet's membrane. Ophthalmic examination should reveal evidence of prior inflammation or glaucoma, and one should assess vision and determine IOP.

15.7 Uvea

15.7.1 ANATOMY

The uvea is the middle, vascular tunic of the eye and comprises the anterior portion, the iris and ciliary body, and the posterior choroid. Histologically, the uvea contains blood vessels, pigment cells, smooth muscle, and in the horse, a noncellular, fibrous tapetum in the choroid. The uvea is the primary site of the blood-ocular barrier, which has importance in the formation of the aqueous humor, serves as a barrier to blood-borne materials, and is an immunologic barrier to the internal components of the eye. Inflammation disrupts this barrier (uveitis). Smooth muscles in the iris and ciliary body, under autonomic control, regulate pupil size and accommodate for near and far vision, respectively. In uveitis, spasm of these muscles results in constriction of the pupil and pain, seen clinically as miosis and photophobia. The ciliary body is the source of aqueous humor, which supplies nutrition to the cornea and lens. Aqueous humor is produced by active and passive processes; its production is decreased by inflammation and by pharmacologic agents used in glaucoma therapy. The choroid supplies nutrition to the retina and also serves as a heat sink to protect the photoreceptors from the heat generated by light striking the retina. The tapetum, contained within the superior choroid, reflects light back across the retina, thereby maximizing the use of available light.

15.7.2 ABNORMALITIES OF THE PUPIL

The pupil of the horse is horizontally elliptic with the dorsal and ventral margins having pigmented prominences termed *corpora nigra*. The pupillary light reflex in the horse is similar to that of other species with a direct and a consensual response. The afferent fibers of the pupillary light reflex are carried in cranial nerve II, and the efferent parasympathetic fibers are carried in cranial nerve III. Abnormalities in pupil response to a light stimulus result from afferent lesions involving the retina or optic nerve. Afferent abnormalities are associated with loss of vision in the affected eye. Efferent lesions are rare but include damage to cranial nerve III with an associated ventrolateral strabismus, abnormalities of the iris itself as with synechiae, and glaucoma. One also must differentiate excited horses with sympathetic override, weak light source, and improper examination technique from an abnormal pupillary light response.

Sympathetic nerve fibers supply the dilator muscles of the iris. These fibers travel in the spinal cord, emerge in
the ventral nerve roots at first and second thoracic nerves, course through the thorax, run in association with the
internal carotid artery, synapse at the cranial cervical sympathetic ganglion, and travel to the eye with the ocular 1011
arteries. Damage to the sympathetic fibers results in Horner's syndrome. Clinical signs include ptosis, miosis, 1012
enophthalmos, protrusion of the third eyelid, and sweating on the affected side of the face and neck. One directs
treatment toward the primary disease, if possible. In some horses the clinical signs of Horner's syndrome
resolve without treatment.

15.7.3 UVEAL CYSTS

Cysts of the anterior uvea (iris, corpora nigra, and ciliary body) have been reported in the horse.[64,65] The cysts are usually heavily pigmented and may not transilluminate, making a uveal melanoma the most likely differential diagnosis. Ocular ultrasonography reveals these as cystic structures and confirms the diagnosis.

Treatment is not required unless the cysts are numerous or impair sight. One can collapse the cyst or aspirated it by paracentesis or, if available, disrupt it using laser energy delivered transcorneally.[65] One can deliver diode laser energy to the cyst through the cornea using an indirect ophthalmoscope and a 20-D condensing lens. One performs the procedure on the standing horse and photocoagulates the cyst wall, shrinking the cyst and preventing recurrence.

15.7.4
ANTERIOR SEGMENT DYSGENESIS

Anterior segment dysgenesis has been described in the Rocky Mountain horse, Kentucky Saddle horse, and Mountain Pleasure horse breeds. The abnormalities associated with this syndrome include macropalpebral fissure, megalocornea, ciliary body and peripheral retinal cysts, congenital miosis, iris stromal hypoplasia, iridocorneal angle abnormalities, cataract, retinal dysplasia, and retinal detachment.[66] The abnormalities appear linked to coat color with the highest prevalence of abnormalities associated with chocolate coat and white mane and tail.

15.7.5
UVEITIS

Uveitis is an inflammation of the iris and ciliary body (anterior) and choroid (posterior). Uveitis is a common manifestation of many ocular and systemic infectious and noninfectious diseases, and as such, an attempt to ascertain the cause is essential. Differentiating uveitis from other ophthalmic diseases resulting in a red and painful eye, such as glaucoma, corneal ulceration, and conjunctivitis is also essential. Uveitis is reported as the leading cause of blindness in horses throughout the world.[44,67]

15.7.5.1
Clinical Signs

Acute inflammation of the anterior uvea results in spasm of the iris and ciliary muscles, which is apparent clinically as miosis and photophobia, and a breakdown in the blood-ocular barrier (Box 15-3). The primary mediators of intraocular inflammation are prostaglandins. Eyelids and conjunctiva may be swollen and hyperemic in the acute phase of anterior uveitis. Protein and cells leak into the anterior chamber, resulting in aqueous flare, hypopyon, and keratitic precipitates. Chronic inflammatory changes in the aqueous humor can result in secondary corneal endothelial and lens changes (e.g., corneal edema and cataract) and adhesions between the iris and adjacent lens or cornea, termed *synechiae* (Figure 15-10). Inflammation of the choroid, because of its close association with the retina, usually also involves the retina and is termed *chorioretinitis*. Chorioretinitis is diagnosed by direct or indirect ophthalmoscopy and results in retinal and subretinal transudate and exudate, retinal vascular changes, hemorrhage, retinal detachment, and retinal degeneration. Choroidal depigmentation and areas of repigmentation or pigment clumping may be present (Figure 15-11). Other chronic changes resulting from intraocular inflammation include secondary glaucoma, blindness, and phthisis bulbi. The development of intraocular changes following uveitis is related directly to the duration and severity of the acute episode and is exacerbated by recurrent episodes of inflammation.

15.7.5.2
Causes

The causes of anterior and posterior uveitis include primary ophthalmic and systemic diseases.[23] Blunt or 1012
penetrating ocular trauma, intraocular neoplasia (primary or secondary), corneal ulceration, parasitic 1013
infiltration, and numerous systemic infectious diseases with associated septicemia, toxemia, immune-complex disease, and viremia are associated with uveitis. Of the systemic infectious diseases implicated in equine uveitis, infections of *Streptococcus equi* (strangles) and *Leptosprira interrogans* serogroup *pomona*[68,69] and gram-negative sepsis occur most commonly. In addition to a complete ophthalmic examination, evaluating the entire animal through a complete physical examination and appropriate laboratory testing is essential. A complete ophthalmic evaluation must include fluorescein staining of the cornea; penlight examination to evaluate pupil size, aqueous humor content, lens position and transparency; and direct and consensual pupillary light responses. Direct (with or without indirect) ophthalmoscopic

examination of the fundus is also essential. Failure to perform these routine diagnostic tests results in misdiagnosis and incorrect therapy and may result in a failure to consider and examine for systemic disease, thereby placing the health of the animal in jeopardy.

Figure 15-10 Numerous posterior synechiae and a cataract occur following chronic anterior uveitis. The corpora nigra are adhered to the anterior lens and result in distortion of the pupil margin.

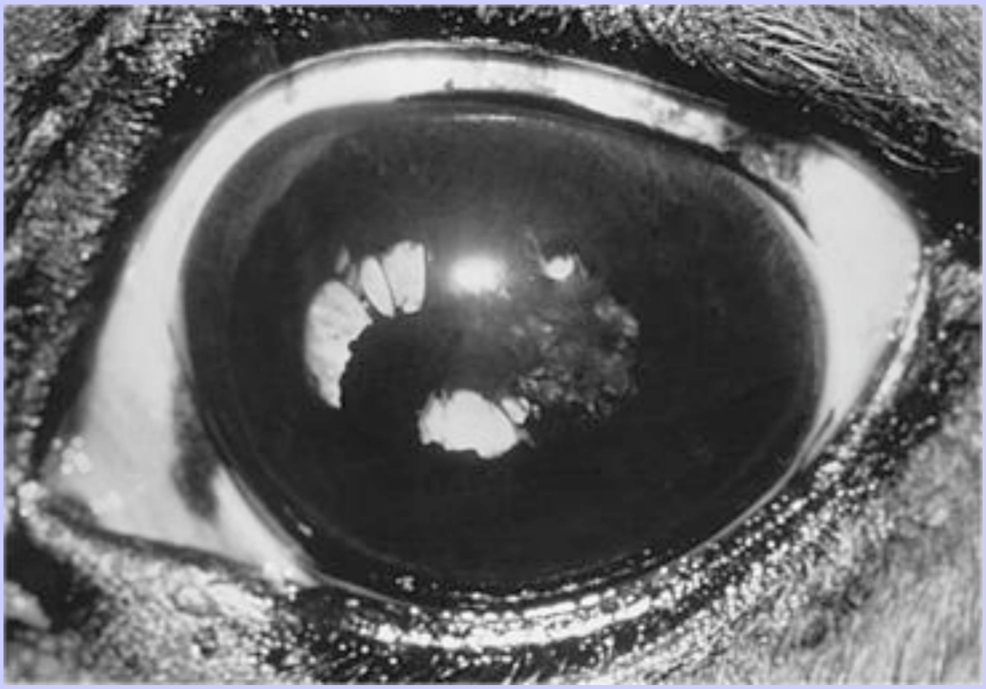

Figure 15-11 Peripapillary depigmentation, a so-called butterfly lesion, associated with the chorioretinitis of equine recurrent uveitis.

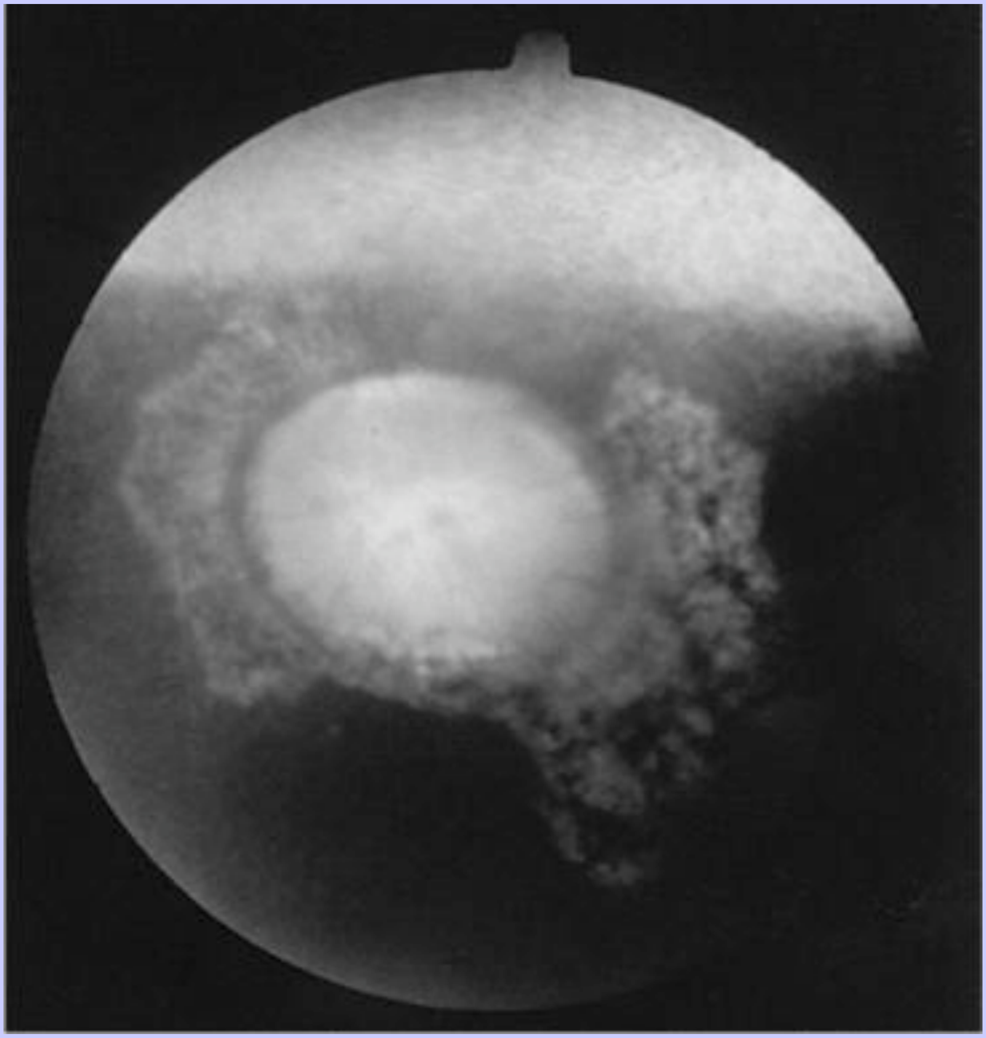

Primary ophthalmic diseases that result in anterior uveitis include corneal ulceration, lens-induced uveitis, intraocular neoplasia and direct ocular trauma. Corneal ulceration results in secondary anterior uveitis through a reflex pathway involving the ophthalmic branch of cranial nerve V. Fluorescein staining of the cornea therefore is indicated in eyes with anterior uveitis. The lens is considered to be an immune-privileged site and as such is capable of stimulating an inflammatory reaction. Lens protein is exposed by traumatic rupture of the lens capsule or during the degenerative process of a hypermature cataract undergoing liquefaction and leakage. Either of these processes can lead to anterior uveitis with rupture of the lens resulting in the more severe inflammation and, frequently, secondary glaucoma. Uveitis resulting from direct ocular trauma may be associated with rupture of the fibrous tunic of the eye, hyphema, lens luxation, corneal endothelial damage, retinal detachment, or proptosis. A complete ophthalmic examination is essential. If the anterior and posterior segments of the eye are not completely visible, then an ocular ultrasound examination is indicated, specifically to evaluate the position of the lens and retina and to look for changes in the

echogenicity of the vitreous humor. In addition to a complete ophthalmic evaluation, one must examine the entire animal for signs of trauma to other body systems. Fractures and soft tissue damage of the head and neck, thoracic and abdominal trauma, fractures of the limbs, and neurologic changes involving the central nervous system are potential complications associated with ocular trauma.

Systemic diseases resulting in anterior and posterior uveitis are numerous and include bacteremia, septicemia, disseminated mycoses, and the syndrome of equine recurrent uveitis. Infection with *Borrelia burgdorferi* has been reported to result in arthritis and panuveitis in a pony.[70] Foals with neonatal septicemia are especially prone to anterior and posterior uveitis. The uveitis in these foals is usually sterile. Systemic antimicrobial, topical and systemic antiinflammatory, and topical atropine 1% therapy are the treatments of 1013
choice. Copious fibrin production may result from anterior uveitis, especially in young foals, and can result 1014
in posterior synechia and opacification of the lens capsule. Intracameral tissue plasminogen activator, 25 to 75 μg administered in the first few days after fibrin formation, can result in complete lysis and resolution.

15.7.5.3 Equine Recurrent Uveitis

Equine recurrent uveitis (ERU; moon blindness, periodic ophthalmia) is the most common cause of blindness in horses, with Appaloosas at increased risk compared with non-Appaloosas.[69] ERU is an immune-mediated disease with numerous initiating or exacerbating factors[3,68,71] (Box 15-4). The clinical signs of ERU are similar to those of other causes of uveitis, the distinguishing feature being its recurrent nature. The frequency and severity of each recurrence vary greatly. Even in times of clinical quiescence, inflammation is believed to continue at a subclinical level, resulting in further intraocular damage. Diagnosis is based on history and clinical examination. Although serologic evaluation for *Leptospira* species, *Brucella* species, or *Toxoplasma* and conjunctival biopsies to evaluate for the presence of *Onchocerca cervicalis* have been advocated,[3] the results of these tests rarely alter individual therapy, in part because of the chronicity of the disease and because the inciting cause may have begun years before development of uveitis.

One directs treatment of the individual horse toward suppressing inflammation, controlling pain, and preventing sequelae. In situations in which the prevalence of ERU in a barn exceeds that normally expected, serologic testing and examination to attempt to determine the cause is indicated. Routine vaccination for *Leptospira* species is controversial and may be contraindicated in horses with active inflammation.

The prognosis for ERU varies according to the severity of uveitis, duration of episodes, response to treatment, and frequency of recurrence. Each episode results in some degree of intraocular damage, and damage to the corneal endothelium, lens, and retina is cumulative because repair of these tissues is difficult. In addition, damage often occurs at a subclinical level during the so-called inactive periods. One should consider horses with evidence of previous uveitis, corneal edema, cataract, synechiae, pigment on the anterior lens capsule, atrophy of the corpora nigra, and degeneration of retina and optic nerve as ophthalmologically unsound. One must consider all animals that have had an episode of acute uveitis at risk to develop chronic recurrent uveitis. All animals with chronic recurrent uveitis have a guarded prognosis for long-term maintenance of normal vision, with blindness often being the end result.

Treatment

The treatment of any uveitis, acute or chronic, involves specific therapy determined by the cause of the uveitis and nonspecific therapy designed to decrease inflammation, pain, and prevent further intraocular damage. The initiation of specific therapy depends on correctly identifying the cause, whether a primary ophthalmic disease or a systemic problem. Failure to control intraocular inflammation may lead to severe secondary ophthalmic complications such as glaucoma, synechiae, cataract, retinal detachment, phthisis bulbi, and blindness.

Nonspecific therapy includes topical and systemic corticosteroids and NSAIDs to decrease inflammation and atropine to dilate the pupil and decrease the pain of ciliary muscle spasm. Selection of medication, frequency of treatment, and route of administration depend on the cause and severity of the uveitis and whether the uveitis is anterior, posterior, or both.

Topical medications for treating anterior uveitis include atropine, corticosteroids, cyclosporin A, and NSAIDs. One administers topical atropine 1% as needed to dilate the pupil, but generally not more than 4 times a day. One should monitor intestinal motility because topical atropine can result in ileus and colic. Topical corticosteroids are useful, provided corneal ulceration is not present as determined by fluorescein stain. Prednisolone acetate 1% ophthalmic is the corticosteroid of choice because it achieves the highest intraocular levels. Alternatively, one can use dexamethasone 0.1% ophthalmic solution or 0.05% ointment. Frequency of administration varies according to severity, with initial frequency being every 4 to 6 hours and subsequently decreased as the eye responds to therapy. One should continue topical corticosteroid therapy for several weeks after resolution of clinical signs. In addition, subconjunctival corticosteroids have been advocated in severe cases of anterior uveitis[3,44] (see Table 15-3). Topical NSAIDs are available, but little 1014
information exists regarding their efficacy for treating ERU. The author's experience suggests some efficacy, 1015
but significantly less clinical response than with topical corticosteroids. One can use topical NSAIDs in horses with anterior uveitis and associated corneal ulceration with less risk than corticosteroids. Topical corticosteroids and NSAIDs have a synergistic effect and can be used in combination. Topical antibiotics are not required unless a corneal ulcer is present; corticosteroids then are contraindicated. Topical cyclosporin A 0.2% ointment (Optimmune, Schering-Plough, Kenilworth, New Jersey) may be efficacious for treating active uveitis and as a long-term treatment to decrease the frequency and severity of subsequent recurrences.[46] Unfortunately, although cyclosporine is the drug of choice, it has limited ability to penetrate the intact cornea and reach target tissues.

One uses systemic NSAIDs with topical therapy. Flunixin meglumine is the systemic NSAID of choice for acute ocular inflammation and can be used safely in the presence of corneal ulcer. Alternatively, one can use phenylbutazone or aspirin. Chronic oral administration of aspirin at 25 mg/kg every 24 hours has been advocated to decrease the frequency and severity of recurrent episodes of uveitis.[3] One should place horses with active uveitis in a darkened stall to decrease discomfort and limit exercise.

Recently, surgical management of ERU has been advocated. Surgeries include intravitreal placement of a sustained-release cylosporine-impregnated device[72–74] or vitrectomy.[75] Implantation of a 4-μg/day intravitreal cyclosporin A implant decreased the frequency and severity of recurrent uveitis episodes in 23 horses with a mean follow-up of 1 to 29 months (mean 10.5 ± SD 7.6 months).[72,74] Of the treated horses, 18 of 23 (78.2%) had sight at the time of follow-up. Complications of the intravitreal cyclosporin A implant include glaucoma and retinal detachment, both of which may relate to ERU. Compared with intravitreal cyclosporin A implantation, pars plana vitrectomy is a more invasive surgery, requiring more instrumentation and expertise and is associated with significant postoperative vision-threatening complications. Pars plana vitrectomy does appear, however, to decrease the severity and frequency of ERU episodes.

15.7.6 GLAUCOMA

Glaucoma is an elevation of IOP to a level incompatible with the health of the eye. Equine glaucoma is secondary in virtually all cases, typically resulting from ERU.[76] The reported normal IOP in the horse varies according to the technique used and whether sedation is used, with sedation resulting in a decrease in IOP. One should perform an auriculopalpebral nerve block before determining IOP in the horse. Normal values are reported to range from 20 to 30 mm Hg. Measurement of IOP in the horse presents a challenge in that indentation tonometers, such as the Schiøtz, are not well suited for use in the horse. Applanation tonometers, especially portable devices such as the Tonopen, are best suited for determining equine IOP. In the author's practice, determination of IOP is a routine part of a complete ophthalmic examination. If one plans to determine IOP in the horse, one should remember that intravenous administration of xylazine significantly lowers the IOP.[3]

Although congenital glaucoma (megaloglobus) has been reported in the horse, secondary glaucoma resulting from anterior uveitis, especially ERU, is the most common cause of equine glaucoma.[76] The clinical signs of glaucoma in the horse are often more subtle than in other species. Acute glaucoma may result in pain (photophobia, blepharospasm, lacrimation), corneal edema, linear corneal opacities (striae), mydriasis (provided uveitis or posterior synechiae are not present), and decreased menace response. The linear opacities in equine glaucoma often extend from limbus to limbus and are areas of thinning of Descemet's membrane.[77] Similar linear opacities also occur in normal horses, have been termed *band keratopathy,* and are not significant. In chronic glaucoma, corneal edema and corneal striae may be visible. Enlargement of the globe (buphthalmos), retinal degeneration, and blindness also occur.

Unfortunately, most horses with glaucomatous eyes are presented late in the disease, resulting in a poor response to therapy. Medical treatment of acute glaucoma involves topical agents such as timolol maleate 0.5% (Timoptic, Merck & Co., Inc., West Point, Pennsylvania), dorzolamide 2% (Trusopt, Merck), and the combination of these two drugs (Cosopt, Merck).[78,79] One administers these drugs alone or in combination 2 to 3 times daily in an effort to reduce IOP by increasing the outflow and decreasing production of aqueous humor. Of all the topical glaucoma agents, timolol maleate and dorzolamide are most effective in the horse, and the combination is more effective than administration of the two drugs concomitantly.[78] In the horse, because of

the large percentage of uveoscleral outflow, careful use of topical atropine may actually reduce IOP in some eyes.[80] Use of atropine is controversial, however. Topical corticosteroids, systemic flunixin meglumine, or combined therapy is indicated to control any concomitant inflammation or pain. Failure of topical therapy to control acute glaucoma indicates the need for surgical intervention.

Surgery for the acute glaucoma patient includes transscleral cyclocryosurgery or cyclophotocoagulation using a Nd:YAG or diode laser.[76,81–84] Both procedures are designed to reduce the production of aqueous humor and decrease IOP. Cyclophotocoagulation has fewer intraocular side effects than cyclocryosurgery and is the 1015
surgical treatment of choice. In a retrospective evaluation of 27 horses treated by transscleral diode laser 1016
cyclophotocoagulation, adjunct medical therapy was required for 90% of horses and vision was maintained in 64% with a mean follow-up of 33 months (7 to 69 months).[76] Surgical filtering procedures, designed to provide an alternative outflow pathway for aqueous humor, are generally unsuccessful in the horse.[5]

Treatment of chronic glaucoma is surgical and is designed to reduce discomfort. Enucleation or evisceration with insertion of an intraocular silicone prosthesis is the procedure of choice.[85]

15.7.7 HYPHEMA

Hyphema is blood in the anterior chamber of the eye (see Figure 15-8). As is true of bleeding into other body cavities, blood in the anterior chamber of the eye does not usually clot. One must keep in mind that not all hyphema results from ocular trauma. One must consider systemic diseases that result in clotting disorders or intraocular inflammation.

If the hyphema is complete and precludes the evaluation of intraocular structures, ocular ultrasound is indicated to assess the lens position, retina, and posterior eye wall. The greatest resolution in ocular ultrasound is achieved with a 10-MHz or, if unavailable, a 7.5-MHz probe. One places the probe directly on the cornea or images through the eyelid or an offset device. Provided no other intraocular damage is evident, hyphema will resolve, often without significant sequelae. If associated intraocular damage has occurred, potential sequelae include cataract, posterior synechiae, glaucoma, retinal detachment, and blindness (Figure 15-12).

Figure 15-12 Ocular ultrasonography using a 7.5-MHz probe. A retinal detachment is visible with the retina remaining attached at the optic nerve and ciliary body.

When hyphema results from a traumatic event, concurrent anterior uveitis is usually present. Although hyphema usually does not require therapy, the associated anterior uveitis does. As previously discussed, one treats anterior uveitis with topical atropine and systemic flunixin meglumine. If no corneal ulcer is associated with the hyphema, one also may administer topical corticosteroids. Resolution of hyphema may require 7 to 21 days; to decrease the incidence of rebleeding, the horse should not be exercised during this time. Surgical intervention to remove the hyphema rarely, if ever, is indicated. In instances in which lysis of a clot is beneficial, intracameral injection of tissue plasminogen activator (25 μg) (Activase, Genentech, Inc., South San Francisco, California) may be indicated.[86]

15.8 Lens

The lens originates from surface ectoderm and is a clear, avascular, biconvex structure suspended posterior to the iris by lenticular zonules arising from the ciliary body. The lens depends on the aqueous and vitreous humors to supply nutrition and remove waste products. One should examine the lens in a darkened environment following dilation of the pupil with tropicamide 1.0% (Mydriacyl, Alcon Laboratories). Using a bright focal light source, one evaluates the lens for size, shape, location, and transparency. In addition, a new handheld, monocular slitlamp that attaches to an otoscope or ophthalmoscope handle is available (HSL-10) and provides magnification and an

appreciation for depth and three-dimensional anatomy of the lens and anterior segment. Abnormalities of the lens include congenital malformations, cataract, and luxation.

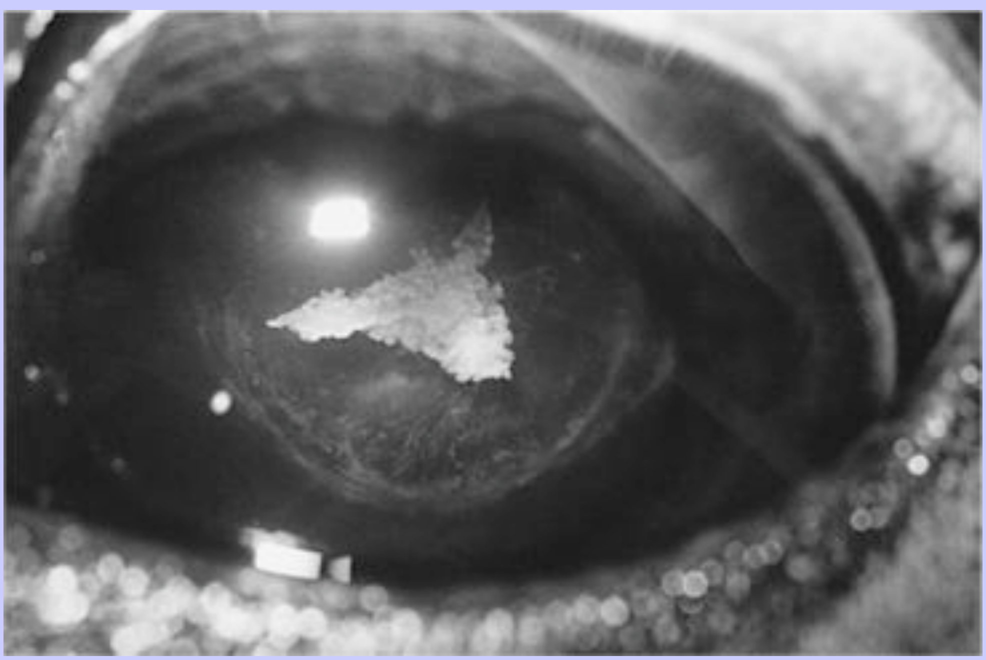
15.8.1 CONGENITAL

Congenital disorders of the lens, other than cataract, are rare. Abnormalities of size (aphakia, microphakia), shape (coloboma, spherophakia), and location (luxation) generally are associated with other ocular abnormalities such as microphthalmos, retinal dysplasia, or retinal detachment. These abnormalities can be uni- or bilateral and may or may not be inherited. Treatment usually is not required except for cataract and luxation. One should discourage breeding of affected animals.

15.8.2 CATARACTS

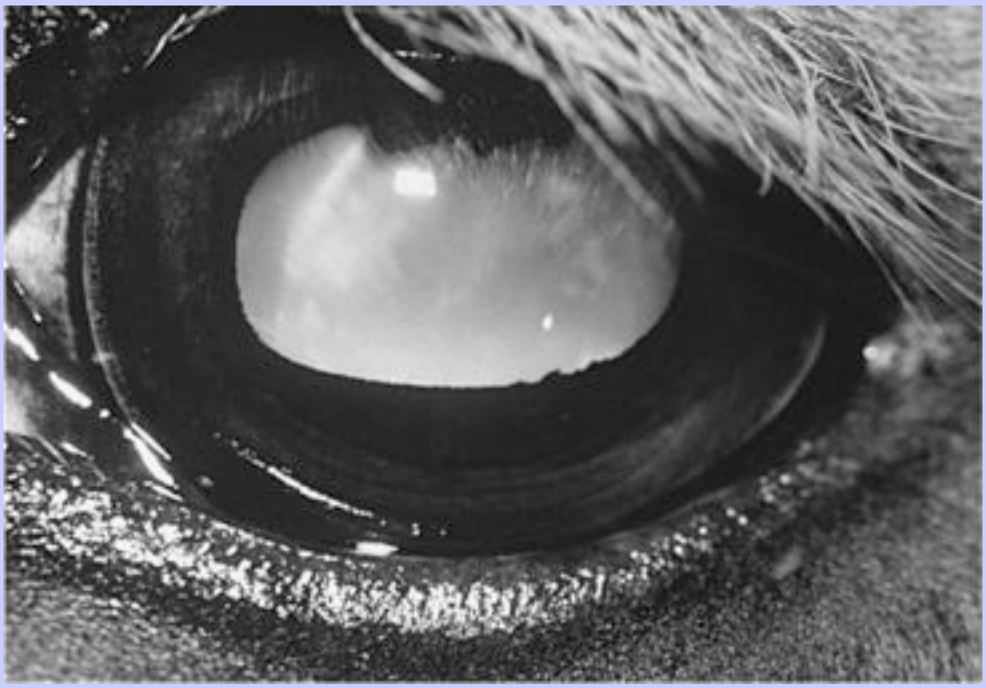
A cataract is any opacity, of any size, involving the lens or its capsule (Figures 15-13 and 15-14). Cataracts can be uni- or bilateral and are classified according to location and degree of lens affected (Box 15-5).
Classification helps determine the cause and likelihood of progression and helps one follow progression. These 1016
terms are only descriptive and are not mutually exclusive. For example, one such description might be an 1017
"anterior, cortical, axial, incipient cataract." In general, anterior, cortical, and equatorial cataracts are more likely to progress than are nuclear and posterior cataracts. In addition, cataracts are classified based on age of onset and, if possible, cause. Classification by age of onset includes congenital, juvenile, adult, and senile cataracts. Congenital cataracts are the most common congenital ocular anomaly in the horse, can be unilateral or bilateral, and may affect only the nuclear portion of the lens.[87] Juvenile and adult cataracts, although acquired, are still heritable.

Figure 15-13 An incipient posterior cortical cataract.



Although many causes of cataracts exist in other species, most causes have not been documented in the horse. Potential causes of cataract formation include inherited, inflammatory, traumatic, metabolic, toxic, and nutritional abnormalities. Suspected inherited cataracts have been reported in several breeds of horses (Belgian, Morgan) and are thought to occur in other breeds but are difficult to prove because of the small number of offspring produced. One must remember that inherited cataracts are not necessarily congenital and that not all congenital cataracts are inherited. In general, if one cannot determine a cause of a cataract and intraocular inflammation is not evident, one should discourage breeding of the animal. The most common cause of cataract formation in the horse is ERU.

Figure 15-14 A mature cataract.



15.8.2.1 BOX 15-5 CHARACTERIZATION OF CATARACTS

15.8.2.1.1 ### Location

Capsular

Subcapsular

Cortical

Equatorial

Axial

Nuclear

Anterior/posterior

15.8.2.1.2 Severity

Incipient: earliest form; small vacuoles

Immature: most of lens affected; fundus visible

Mature: entire lens affected; fundus not visible

Hypermature: liquifying lens fibers; leaking through lens capsule

Morgagnian: entire cortex liquified; nucleus settles ventrally

Treatment of cataracts, if required, is surgical. The decision on whether to treat depends on the severity and cause of the cataract and the presence or absence of concomitant ocular disease. Cataracts that are unilateral or not severe enough to interfere significantly with vision generally do not require treatment. Cataracts resulting from intraocular inflammation, such as those associated with ERU, may not be amenable to surgery. However, with the availabilty of a sustained-release cylosporine-impregnated device,[72–74] one can perform cataract surgery along with a partial vitrectomy and implantation of a cyclosporin A device. Treatment of cataracts associated with abnormalities of the retina, such as retinal detachment or degeneration, is not indicated. If the cataracts are bilateral, interfere with vision, and do not result from ERU or other intraocular inflammation, then one can surgically remove the lens and its anterior capsule. Before cataract surgery, one should evaluate retinal anatomy and function using ocular ultrasound and electroretinography. One should operate on foals with congenital cataracts early (<6 months) to avoid possible deprivation amblyopia. Surgery is performed best using phacoemulsification.[88–90] Controversy exists regarding unilateral cataract extraction in horses with a 1017
contralateral normal eye. Because artificial lens implants are unavailable for horses, cataract extraction results 1018
in a significant degree of postoperative hyperopia (farsightedness).[44] Although significant disparity in postoperative vision between eyes must result, one study suggests that such horses perform better following cataract surgery than as unilaterally blind horses before cataract extraction.[88] Cataract surgery is a referral procedure.

15.8.3 LUXATION

Lens luxation and subluxation can be congenital or acquired. Acquired lens luxation results from glaucoma and buphthalmos, trauma, or most frequently, uveitis, especially ERU. Once luxated, the lens can be displaced anteriorly or posteriorly. A posteriorly luxated lens results in liquefaction of the vitreous from lens movement. The lens settles inferiorly, may or may not attach to the retina, and generally does not result in significant problems or require therapy. Anterior lens luxation results in anterior uveitis, trauma to the corneal endothelium resulting in diffuse corneal edema, and obstruction of aqueous humor circulation resulting in secondary glaucoma. Treatment of anterior lens luxation is surgical removal using an intracapsular extraction technique, provided the eye is visual. This is a referral procedure. In a blind, painful eye, enucleation or intrascleral prosthesis is the treatment of choice.

15.9 Fundus

One can examine the equine fundus best in a darkened environment following mydriasis. Direct and indirect ophthalmoscopy are useful for examining the equine fundus, although direct ophthalmoscopy is preferable for examining the optic nerve and retinal blood vessels. Examination should include evaluation of the tapetal and nontapetal fundus, retina, retinal blood vessels, and optic nerve. Variations in the normal equine fundus are common, and familiarity with these variations is essential.[16,44,87,91] The horse has a paurangiotic retina (partially vascularized) with 30 to 60 small retinal vessels radiating from the margin of the optic disk. These vessels are visible for a distance of one to two disk diameters. The remainder of the equine retina is avascular, being supplied from the underlying choroidal blood vessels. The optic disk is situated in the nontapetal fundus, is oval, and is salmon-pink. The fundus is divided into tapetal and nontapetal regions. The tapetum is situated in the dorsal fundus and is responsible for the characteristic yellow-green of this portion of the fundus. Variations in tapetal color are related to coat color and include yellow, orange, and blue-green.[16,87] The tapetum of the horse is fibrous and is penetrated by small choroidal vessels that appear as dark dots in the tapetum, termed the *stars of Winslow*. The ventral, nontapetal fundus is generally dark brown or black but can appear lighter or nonpigmented depending on coat color.[16,87]

Abnormalities on fundic examination include changes in size, shape, and color of the optic nerve and retinal vessels, elevation or depression of the optic nerve, hemorrhage, changes in tapetal reflectivity (hyper- and hyporeflective), and changes in pigmentation. Hyperreflection abnormalities often indicate thinning or loss of retinal tissue. Hyporeflective changes can indicate an increase in tissue thickness resulting from cellular infiltrates, edema, or folding of the retina, as in retinal dysplasia. Inflammation can result in depigmentation and pigment clumping in the nontapetal fundus and hyperpigmentation in the tapetal fundus. Equine motor neuron disease has been described to result in a mosaic pattern of yellow-brown pigmentation in the tapetal fundus accompanied by a horizontal band of pigment at the tapetal-nontapetal junction.[92]

15.10 Retina

15.10.1 CONGENITAL STATIONARY NIGHT BLINDNESS

Equine night blindness is a bilateral, congenital, nonprogressive retinal disease of Appaloosa horses. The degree of visual disturbance varies among horses, with mildly affected horses exhibiting signs only in dark conditions, whereas severely affected horses are totally blind in the dark, exhibit apprehension in daylight, and may have a bilateral dorsomedial strabismus and nystagmus.[93] The diagnosis is based on history, breed of horse, clinical signs, and maze testing in illuminated and darkened environments, but one must confirm it by electroretinogram because the fundic examination in affected horses is normal. Electroretinography demonstrates an almost purely negative waveform in the scotopic (dark-adapted) response, characteristic of equine night blindness.[93,94] The results of the electroretinogram indicate an abnormality in signal transmission from the photoreceptor cells to the inner retina.[93] Although the inheritance of equine night blindness in the Appaloosa is not defined completely, the disease is suspected to be an autosomal recessive disease. No treatment is available.

15.10.2 CHORIORETINITIS

Inflammation of the retina and choroid in the horse most often results from ERU and may be associated with concomitant optic neuritis. In addition, the vascular nature of the choroid results in susceptibility to blood-borne disease, as with bacteremia, septicemia, and viremia, and most often occurs in foals with pneumonia, strangles 1018
(Streptococcus equi), and other severe infectious diseases. Inflammation of the anterior portions of the eye, 1019
anterior uveitis, often is associated with chorioretinitis. Treatment of chorioretinitis includes systemic therapy for the primary infectious disease, if present, and flunixin meglumine to decrease inflammation. Topical treatment is indicated only with anterior uveal involvement. The sequelae of chorioretinitis include retinal degeneration, retinal detachment, and optic nerve atrophy.

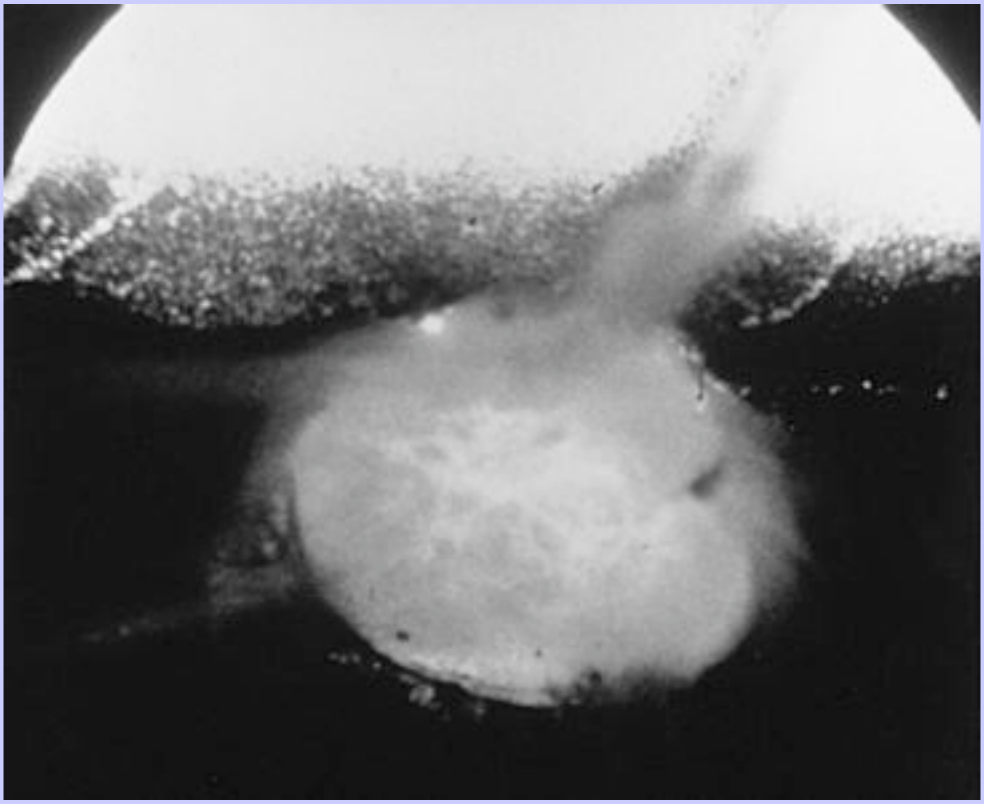
15.10.3 RETINAL DETACHMENT

Retinal detachment can be congenital or acquired, partial or complete (Figure 15-15). Because the equine retina depends almost totally on the underlying choroid for its blood supply, detachment results in rapid and severe retinal degeneration. Common causes of retinal detachment in the horse include an inherited abnormality (associated with retinal dysplasia), ERU, and trauma. Congenital retinal detachment often is associated with other ocular abnormalities. Hyphema may be associated with traumatic detachment, requiring ocular ultrasonography for definitive diagnosis. Treatment is limited to controlling the inciting disease and use of systemic antiinflammatory drugs.

15.10.4 PHOTIC HEAD SHAKING

A condition of head shaking induced by exposure to light and eliminated by blindfolding, darkened environment, and contact lenses has been reported in the horse.[95,96] The problem usually occurs in the spring and summer, is exacerbated by exercise, and may be accompanied by sneezing, snorting, and nasal rubbing. Differential diagnoses for photic head shaking include middle ear disorders, ear mites, guttural pouch mycosis, other ocular disorders, and nasal and dental disease. Ophthalmic examination in these animals is normal. An optic-trigeminal response is hypothesized to occur with optic stimulation, resulting in referred stimulation in areas innervated by the trigeminal nerve.[95]

Figure 15-15 Gray folds of retina are visible overlying and adjacent to the optic nerve, indicating retinal detachment.



Treatment using cyproheptadine at 0.3 mg/kg (Sidmark Laboratories Inc., East Hanover, New Jersey) orally every 12 hours has been effective in several horses.[95,96] Cyproheptadine is an antihistamine (histamine$_1$ blocker) and a serotonin antagonist and is hypothesized to work in photic head shaking by moderating the trigeminal nerve sensation, having a central effect on melatonin, or through anticholinergic activity.[95]

15.10.5 EQUINE MOTOR NEURON DISEASE

Equine motor neuron disease results from a dietary deficiency in the antioxidant vitamin E.[97,98] Ceroid-lipofuscin subsequently accumulates in the retinal pigment epithelium.[97] With ophthalmoscopy, this appears as irregular, sometimes linear accumulations of pigment in the tapetal and nontapetal retina (Figure 15-16, *A* and *B*). The ophthalmoscopic findings, along with appropriate musculoskeletal signs, highly suggest a diagnosis of equine motor neuron disease.

15.11 Optic Nerve

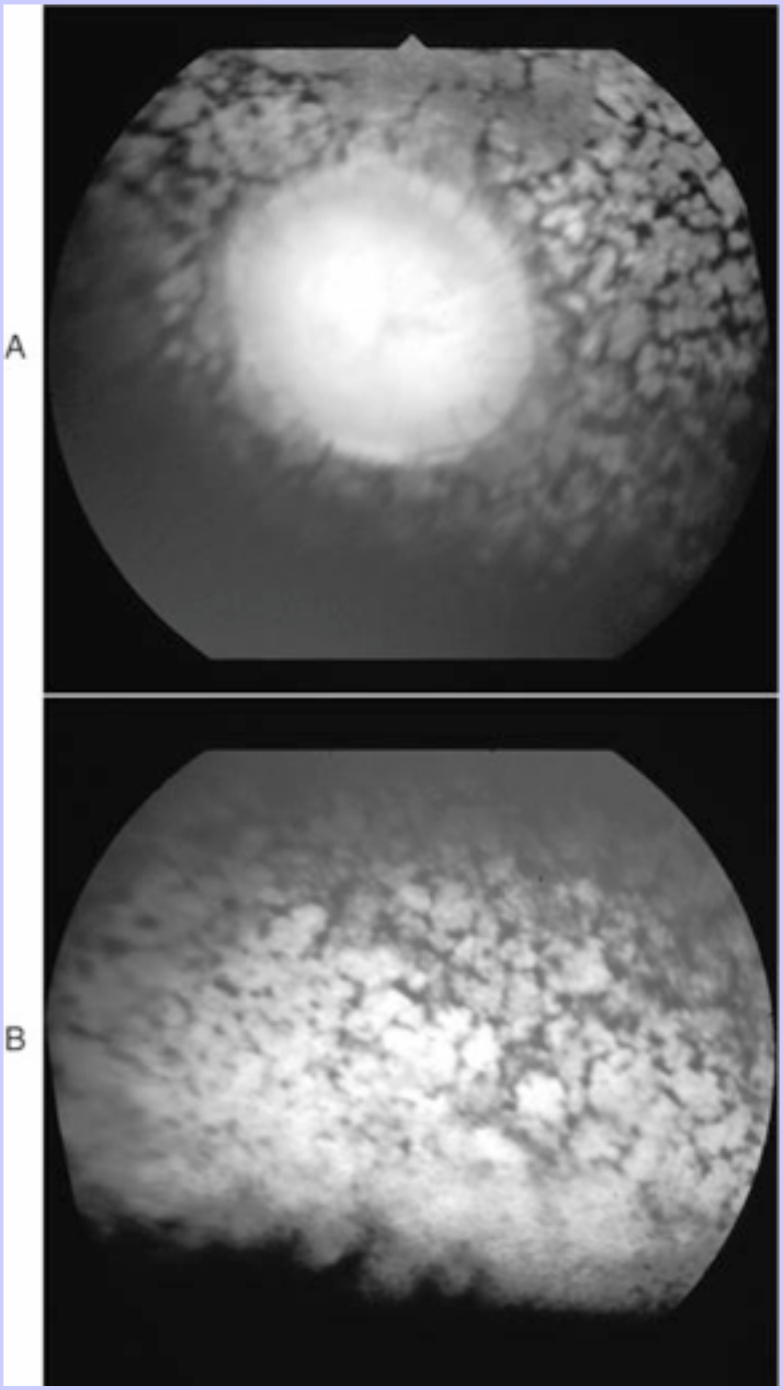
The equine optic nerve is oval, salmon-pink, and located in the nontapetal region of the fundus. Arterioles and venules (30 to 60) extend a short distance from the optic nerve into the surrounding peripapillary retina. On direct

ophthalmoscopic examination the margin of the optic nerve is sharp and well-defined, as are the retinal blood vessels. Often the nerve fiber layer of the retina is visible as linear white streaks radiating outward from the optic nerve. Abnormalities of the optic nerve may appear as indistinct margins, pallor, vascular attenuation, peripapillary depigmentation, edema, hemorrhage, or proliferative changes.

15.11.1 OPTIC ATROPHY

Trauma to the head of the horse has been associated with acute uni- or bilateral blindness resulting from optic nerve damage. The pupil in the affected eye is dilated, but the remainder of the ophthalmic examination may be normal initially. Occasionally, retinal hemorrhage and papilledema are present. Fundic examination 3 to 4 weeks after the traumatic episode reveals optic nerve pallor and absence of retinal blood vessels, indicating atrophy (Figure 15-17). The cause of this lesion is hypothesized to be stretching of the optic nerve with 1019
subsequent rupture of the optic nerve axons[99] or trauma from bony fractures adjacent to the optic nerve. A 1020
small number of these horses may benefit from systemic antiinflammatory therapy in the acute phase. The prognosis, however, is guarded and treatment is usually unrewarding. Optic nerve atrophy also is associated with ERU and results from chronic glaucoma.

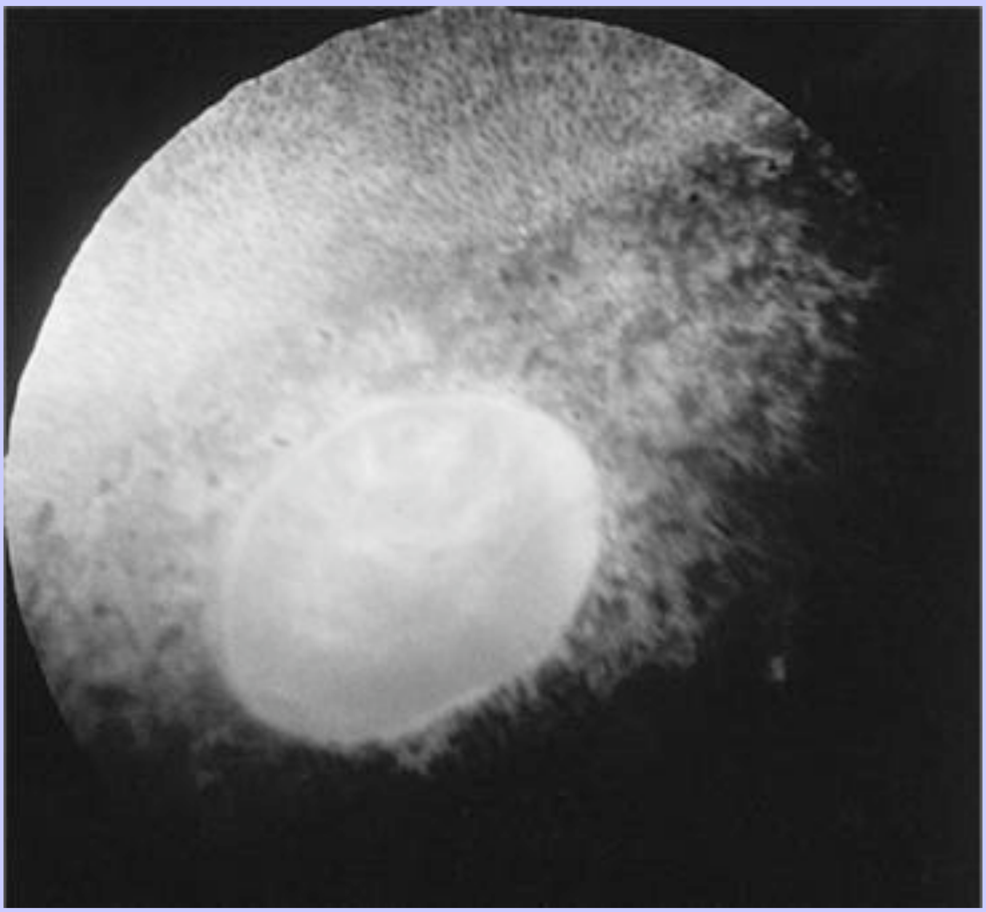
Figure 15-16 **A,** The optic nerve and peripapillary region of horse affected with equine motor neuron disease. The linear accumulations of pigment are ceroid-lipofuscin in the retinal pigment epithelium. **B,** Similar lesions are visible in the dorsal tapetal retina.



15.11.2 ISCHEMIC OPTIC NEUROPATHY

Ischemic optic neuropathy and resulting blindness is described following treatment of guttural pouch mycosis by arterial occlusion. The horses are acutely blind with a fixed and dilated pupil on the affected side immediately following surgery. Blindness is thought to result from ischemia and infarction of the optic nerve and its associated fibers. The initial fundic examination is normal, with abnormalities first seen 3 days following surgery. Indistinct optic disk margins suggesting papilledema or papillitis and raised, white lesions involving the optic nerve are the initial changes.

Figure 15-17 Severe optic nerve atrophy associated with head trauma. The optic nerve is pale, with loss of peripapillary retinal blood vessels. The eye is not visual.



15.11.3 OPTIC NERVE HYPOPLASIA

Horses affected with optic nerve hypoplasia have visual impairment or blindness and slow to absent pupillary light reflexes.[16,87] The abnormality is congenital and can be uni- or bilateral. Optic nerve hypoplasia may be

associated with other ocular abnormalities, including cataracts, retinal detachment, and microphthalmos.[87] The optic disk appears small and pale with fewer retinal vessels than normal. Clinically, optic nerve hypoplasia can appear similar to acquired optic nerve atrophy. One can make a definitive diagnosis on histologic examination. No treatment is indicated, and although the definitive cause is not known, owners should not use the affected horse and possibly the sire and dam for breeding.

Other abnormalities of the optic nerve include bilateral optic neuropathy and blindness following severe hemorrhage[101] proliferative optic neuropathy as in aged horses,[102] neoplasia of the optic nerve,[103] and optic neuritis, which may be associated with ERU. 1020

1021

15.12 Orbit

The horse has a complete bony orbital rim composed of the frontal, lacrimal, zygomatic, and temporal bones. The caudolateral and ventral walls of the equine orbit are fasciae. Abnormalities of the equine orbit most often result from trauma. The zygomatic arch and supraorbital process of the frontal bone and the medial orbital wall are most susceptible to injury. Damage to these areas can involve the supraorbital foramen and its associated nerve or the osseous portion of the nasolacrimal system, respectively.

The diagnosis of an orbital fracture is based on history, clinical signs, and radiographs. Radiographic evaluation of the equine orbit is technically difficult and often unrewarding. Oblique views, highlighting the area of greatest concern, usually are required. One must take care to evaluate the paranasal sinuses—the frontal, maxillary, and sphenopalatine—especially when subcutaneous emphysema is present.

Traumatic fractures of the orbit often are associated with concomitant injury of the globe and adnexa. Complete ophthalmic examination is essential and must include assessment of facial symmetry, vision (menace response, maze testing), pupillary light reflex, fluorescein staining for the presence of a corneal ulcer, examination of the anterior chamber for hyphema and anterior uveitis, fundic examination evaluating the retina and optic nerve, assessment of globe and eyelid mobility, and nasolacrimal irrigation. Head trauma in the horse has been reported to result in acute blindness with fixed, dilated pupils resulting from optic nerve compression, stretching, or avulsion. In those eyes in which ocular damage precludes examination of the posterior segment, ocular ultrasound examination is advisable.

Blunt trauma to the orbit can result in a breakdown of the fibrous orbital septum and subsequent herniation of orbital fat. Clinically, the condition is a nonpainful swelling that appears at the time of, or following, orbital trauma and is treated best surgically, removing or replacing the herniated portion of the orbital fat pad and attempting to repair the rent in the septum.

Traumatic proptosis is rare in the horse because of the complete bony orbital rim. If the globe protrudes, it indicates severe head trauma, and thorough physical and neurologic examinations are required. Provided the optic nerve and extraocular muscles are intact, one should replace an exophthalmic globe, a procedure that requires general anesthesia. Once one replaces the globe, one performs a temporary tarsorrhaphy to protect the eye until the swelling subsides. Systemic antibiotics and antiinflammatory drugs are indicated to control postoperative complications.

Treatment of orbital trauma in the acute phase includes systemic antiinflammatory therapy, systemic antibiotics, especially if a paranasal sinus is involved, and cold compresses. The antiinflammatory drug of choice is systemic flunixin meglumine. Local therapy is required to manage corneal exposure, ulceration, and anterior uveitis. If eyelid movement is impaired because of neurologic dysfunction or swelling of the eyelids, one must protect the

cornea from exposure and desiccation using a topical, sterile ophthalmic lubricant applied as frequently as possible, or in the more severe cases, by using a temporary tarsorrhaphy. Topical broad-spectrum antibiotics are indicated in horses with corneal ulceration, and atropine relieves the discomfort associated with anterior uveitis.

Although facial and orbital fractures in horses often heal without surgery, they may do so in a manner that results in deformity and interferes with the normal function of the eye and adnexa. Therefore surgical correction may be indicated, especially in those fractures that are displaced. One must consider fractures that extend into a paranasal sinus as open fractures, because these sinuses contain resident bacterial and fungal flora. Early repair is associated with a more favorable cosmetic result, for skull fractures consolidate rapidly and the resulting fibrous callus may interfere with surgical reduction. Generous skin flaps in the surgical approach are advised because fractures are often more extensive than initially thought. One should avoid excessive periosteal dissection because periosteum provides stability and blood supply to the damaged area.

Orbital neoplasia is rare and may result in exophthalmos, strabismus, and vision and pupil abnormalities. Skull radiographs, orbital ultrasound, cytologic examination of a fine-needle aspirate, and histopathologic examination are useful in confirming the diagnosis. SCC, lymphosarcoma, adenocarcinoma, medulloepithelioma, melanoma, and tumors of neuroendocrine origin have been described.[104] Differential diagnoses include trauma and orbital abscess and cellulitis. Because most horses are presented late in the course of disease, orbital exenteration is often the treatment of choice. If one suspects an orbital neurendocrine tumor, one must take care during enucleation/exenteration because extensive intraoperative hemorrhage is frequent.

A technique for radical enucleation/exenteration with partial orbital rim resection, mesh skin expansion and second intention healing has been described recently for extensive periocular tumors in horses.[105] This technique is indicated when skin is insufficient to complete a standard primary closure following surgical resection.

16 CHAPTER 16 DISORDERS OF THE REPRODUCTIVE SYSTEM

Grant S. Frazer

16.1 16.1—Reproductive Anatomy and Physiology of the Nonpregnant Mare

Daniel C. Sharp

Michael B. Porter

Equine reproductive physiology deviates from other domestic and companion animal models, often providing the open-minded practitioner and researcher a lifetime of challenges or frustrations, depending on their approach to them. This chapter presents the authors' current understanding of equine reproductive physiology set against a backdrop of accepted dogma for other species as often as appropriate.

16.1.1 Seasonal Reproductive Cycle

A dominant and often troublesome feature of equine reproduction is the adherence to an annual rhythm of reproductive competence and incompetence. The annual reproductive cycle of mares reflects an evolutionary strategy to maximize survival of foals by programming the breeding season attuned to gestation length. Thus mares, with approximately 11 months gestation, begin to breed in the midspring so as to time parturition in midspring. Therefore the mechanisms best able to regulate timing of the annual reproductive cycle are long-term and highly reliable. Nutritional and environmental temperature changes do not fit that requirement well. The four main phases of the annual reproductive rhythm are discussed next.

16.1.1.1 ANESTRUS

Anestrus usually occurs during the shortest days of winter and is characterized by reproductive incompetence in most mares. Measurements of hypothalamic gonadotropin-releasing hormone (Gn-RH)[1–4] indicate a low hypothalamic Gn-RH content and secretion rate during anestrus. Pituitary gonadotropin secretion consequently is reduced, with low or undetectable circulating concentrations of luteinizing hormone (LH) and follicle-stimulating hormone (FSH).[5–7] Although pituitary stores of FSH appear to be adequate throughout anestrus,[8] this is not the case with LH. The messenger RNA (mRNA) encoding LH subunit production becomes undetectable in pituitary tissue during anestrus.[9,10] Thus pituitary gonadotropins (FSH and LH) are low during anestrus because of suppression of the releasing signal from the hypothalamus (Gn-RH), plus inactivation of the gene encoding LH synthesis in the pituitary. The result is, not surprisingly, loss of function of the ovaries. Ovarian activity, including follicular development and hormone production, is minimal, with few follicles greaterthan 5 mm in diameter and undetectable circulating concentrations of estradiol and progesterone.

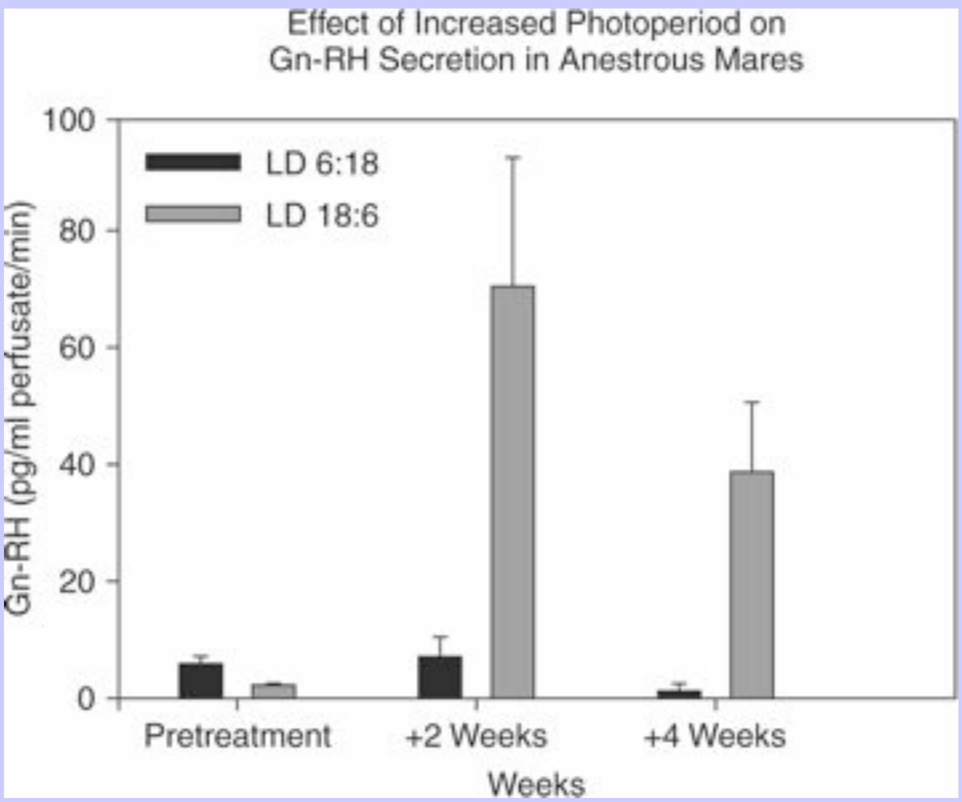
As might be expected from this reduction in circulating hormones, sexual receptivity in mares during anestrus tends to be reduced or lacking altogether. Given the lack of circulating hormones, the passivity of mares in response to teasing not surprisingly is highest in winter.[6] 1025

16.1.1.2 VERNAL (SPRINGTIME) TRANSITION

The vernal transition of the annual reproductive cycle, which begins sometime around the first of the calendar year, is the most troublesome commercially. The first event in transition—likely the initiating one—is an increase in hypothalamic Gn-RH observable within 1 week after the winter solstice[2] or 2 weeks after exposure to an artificially increased photoperiod several weeks before the solstice (Figure 16.1-1).[11] Whether the increase in hypothalamic Gn-RH represents a response to increasing day length, refractoriness to short day length, or some other factor remains unresolved.

Hart, Squires, Imel, et al.[8] reported that the increased Gn-RH secretion shortly after the winter solstice leadsto increased FSH secretion from available pituitary stores, but that LH levels remain low. Sherman, Wolfe, Farmerie, et al.[9] explained this phenomenon, stating that the mRNA encoding LH subunit synthesis was undetectable in the winter and early spring. The third major event during the vernal transition, after hypothalamic Gn-RH secretion and subsequent release of pituitary FSH stores, is follicular development. During vernal transition, the size and number of manually detectable follicles increases.[12,13] The follicular population changes from only two or three small follicles (5 to 10 mm in diameter) to six or more midsize follicles (15 to 25 mm), with the diameter of the largest follicle exceeding 35 to40 mm.[12] A major problem early in the breeding season is that many of these large vernal transition folliclesdo not ovulate. In ponies, an average of 3.5 ± 0.7 large (>30 mm) anovulatory follicles develop in sequence before the first ovulation of the year.[6] These anovulatory vernal transition follicles are the cause of high reproductive inefficiency during the springtime, and one cannot possibly discern, by palpation or ultrasound, whether they will be ovulatory. Consequently, many mares are sent to the stallion inappropriately, adding to the frustration and expense of breeding. Furthermore, mares with chronic failure of uterine clearance likely suffer most from such an inappropriate breeding, and the penalty to the breeder is often greater expense aimed at resolving uterine contamination.

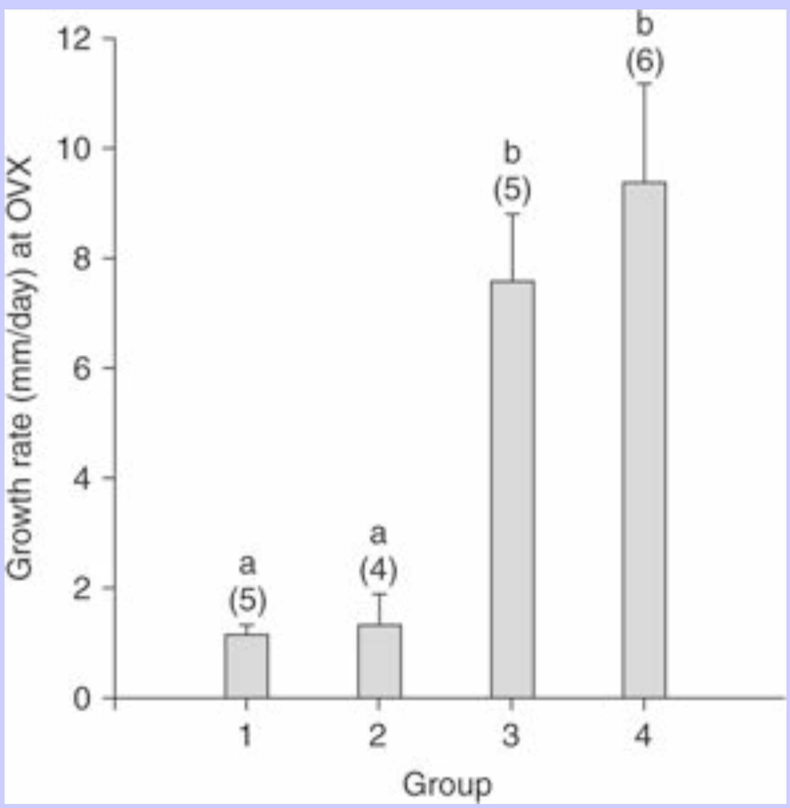
Figure 16.1-1 Gonadotropin-releasing hormone (Gn-RH) secretion (picograms per milliliter per minute, LS means ± SEM) as measured with push-pull perfusion of the pituitary in mares exposed to short photoperiod (LD 6:18, *n* = 4) andin mares exposed to long photoperiod (LD 18:6, *n* = 4) for4 weeks. In the bars marked *pretreatment*, all mares hadbeen exposed to LD 6:18. Subsequently, four mares were exposed to LD 18:6, and Gn-RH secretion was measured at2-week intervals. Time of year the experiment was begun was December 1. Gn-RH was highly significantly elevated in mares after only 2 weeks of photostimulation.



The first several vernal transition follicles are different from fully functional follicles during the breeding season. Although they attain a diameter comparable with preovulatory follicles of the breeding season (>30 mm), they do so much more slowly. Careful tracking of follicles reveals that the first and second large follicle of the year grow at a rate of only 1 to 2 mm per day(Figure 16.1-2), compared with growth rates of about 10 mm per day for follicles that go on to ovulate.[14] Therefore one may assess the potential functional status of springtime follicles by frequently monitoring their growth.

The slower growth rate of vernal transition follicles reflects other metabolic deficiencies, including poor vascularity compared with ovulatory follicles and significantly smaller granulosa cell content.[15] The poor 1026
granulosa cell investment of early vernal transition follicles is significant in that the granulosa cell layer 1027
contributes substantially to the steroidogenic capabilities of the follicle. Thus steroid production by the early vernal transition follicles is limited. The follicles do not produce estradiol, as monitored by peripheral blood, follicular fluid, or in vitro production rate. Estradiol concentration is low or undetectable in peripheral plasma until 5 or6 days before the first ovulation of the year.[7,14,16] One can measure circulating estradiol to discriminate between nonfunctional and functional (ovulatory) follicles.

Figure 16.1-2 Growth rate (millimeters per day) of follicles during vernal transition. Groups represent mares at first, second, third, and fourth follicle of the year. (From Tucker KE, Cleaver BD, Sharp DC: Does resumption of follicular estradiol synthesis during vernal transition in mares involve a shift in steroidogenic pathways? *Biol Reprod* (suppl 1) 48:188, 1993.



When one of the sequential vernal transitional follicles acquires steroidogenic capability, the circulating estradiol increases significantly 5 to 6 days before the first ovulation of the year. The average date for the first ovulation of the year is consistent from year to year, and variance among mares in a population is low. Data collected from as far north as 43 degrees north latitude to as far south as18 degrees north latitude have

indicated an onset of the breeding season (date of first ovulation of the year) to be around the first week of April in mares and the second week of May for pony mares that have not been exposed to artificial lighting. Once the first ovulation of the year has occurred, vernal transition is completed and regular polyestrous cycles occur throughout the late spring and summer in unbred mares.

Renewed LH synthesis and secretion, also manifested by a large surge 5 to 6 days before the first ovulation of the year, is associated with the rise in estradiol. Sharp, Grubaugh, Davis, et al.[17] and Cleaver and Sharp[18] have demonstrated that administration of estrogen advances this secretion of LH in mares during early vernal transition, and Sharp, Wolfe, Cleaver, et al.[10] further demonstrated that estrogen administration to ovariectomized mares at the same time of year stimulated the mRNA encoding for the LH α and β subunits. In other words, estrogen administration was associated with activation of the LH gene. However, as Freedman, Garcia, and Ginther[5] and Peltier, Robinson, and Sharp[7] have demonstrated, the increase in peripheral LH occurs at approximately the same time in mares with and without ovaries. Thus the role of estrogen in bringing about the resurgence ofLH synthesis and secretion remains unclear. Furthermore, one must resist the temptation to use estrogen to hasten LH synthesis in mares during the early vernal transition because of the negative effects of estrogen on FSH secretion. Initiating LH synthesis may be possible, only to find that it inhibits follicular development.

16.1.1.3 BREEDING SEASON

The next section discusses the breeding season in detail. The breeding season is characterized by regularly recurring cycles of estrus and diestrus throughout the summer, unless pregnancy occurs.

16.1.1.4 AUTUMNAL TRANSITION

The transition from reproductive competence in the breeding season to reproductive quiescence characteristic of anestrus is perhaps the least understood part of the annual seasonal reproductive cycle in mares. The period of reproductive decline has a much greater variance during the fall than does the period of reproductive renewal in the spring. The variance is understandable from the evolutionary aspect, because mares likely faced little pressure to reproduce in the fall, for their offspring would face more difficult survival at foaling the next year. Although this is an oversimplification, the autumnal transition may be characterized simply as the gradual loss of gonadotropic support for ovarian function, resulting in reduced follicular development. The final act of the autumnal transition may be development of a large preovulatory follicle that fails to ovulate.[19]

16.1.2 Morphologic Behavioraland Hormonal Changesof the Estrous Cycle

16.1.2.1 ESTRUS

Estrus, defined by receptivity of the mare to a stallion, is characterized by profound changes in the ovaries as follicles develop and in the uterus, cervix, and vagina as the developing follicles begin producing estrogen and by the occurrence of a prolonged surge or increase in LH.

16.1.2.1.1

Behavior

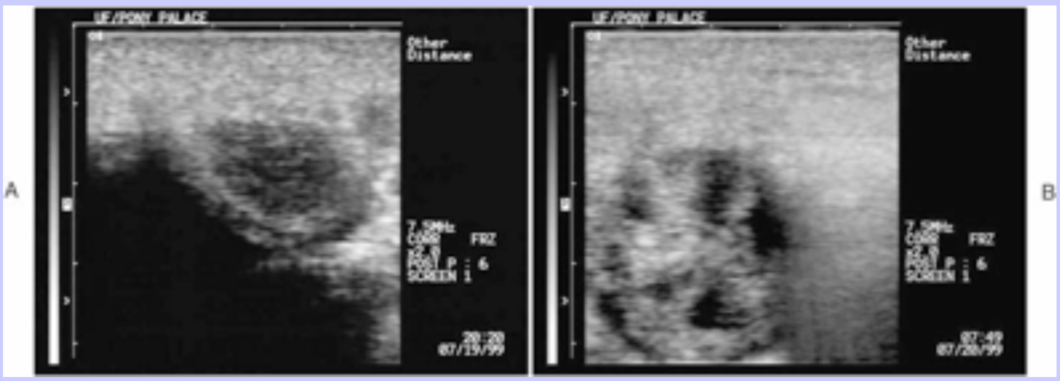
Understanding estrous behavior, as monitored by teasing with a stallion, is an important foundation to any breeding program. *Estrus*, the word coined by Walter Heape,[20] is thought to come from the Greek word *Oestridae*, a genus of the gadfly, because locomotor activity of many female ungulates increases during estrus. Estrous behavior is associated temporally with increasing estrogen concentrations peripherally but also may be associated with the concomitant decline in progesterone levels. Support for the idea that estrogen may not be essential for estrous behavior comes from observations of estrous display in mares with inactive ovaries and from ovariectomized mares during anestrus.[21] The displays of estrous mares reflect a wide range of behaviors and extents, however, and successful breeding farms often owe their success in part to careful monitoring and record keeping for each mare. Among the signs observed during estrus are elevationof the tail in the presence of the stallion, eversion of the vulvar lips to expose the clitoris ("winking"), squatting with rotation of the pelvis, urination, and remainingcalm (i.e., not moving away) in the immediate presenceof a stallion. Recording behavioral signs tends to takethe decision making 1027
out of the watching process, and potentially provides a more precise record of progress through the estrous 1028
cycle.

16.1.2.1.2

Ovarian Morphology

One can use morphologic changes during estrus to monitor the progress toward ovulation. The equine ovary is structurally different from other species in that the cortical elements containing the primordial follicles are located centrally in the ovary instead of peripherally as in all other species that have been studied so far. This central position of potential ovulatory follicles presentsa dilemma in that ovulation cannot occur at the site of follicle development. Most of the surface of the equine ovary is covered with mesothelium, which apparently does not allow the tissue remodeling required for rupture of the follicle. Instead, ovulation in the mare always occurs at a specific site, called the "ovulation fossa," that is located ventrally on the ovary. The bean shape of the equine ovary creates a recessed fossa area in which germinal epithelium is located. This inside-out structure of the mare's ovary likely contributes to some of the unusual aspects of the equine estrous cycle, including the period of prolonged estrus, the large preovulatory follicle size, and the prolonged increase in LH that precedes ovulation. A logical assumption is that the structure of the ovary led to coevolution of a hypothalamic-pituitary axis that was able to present gonadotropins over a prolonged duration. The ovarian structure requires extensive tissue remodeling for a developing follicle to reach the restricted areaof the fossa where it can ovulate. The extended gonadotropin secretion seems likely to be an important part of the tissue remodeling process that precedes rupture of the follicle. Administration of Gn-RH analog to stimulate endogenous LH release, or human chorionic gonadotropin (LH activity), results in increased levelsof tissue remodeling enzymes in the follicle within24 hours.[22] This prolonged process presents challenges to the breeder or veterinary practitioner who is attempting to schedule breeding at a time appropriate to the expected ovulation.

Figure 16.1-3 **A**, Portion of uterine horn showing edema score of 1 (relatively homogeneous pattern with little evidence of fluid). **B**, Portion of uterine horn showing edema score of 4 (marked heterogeneity with clear evidence of fluid-filled lacunae).



16.1.2.1.3

Tubular Reproductive Tract

Perhaps the two most prominent changes in the equine tubular reproductive tract are the appearance of the external portion of the cervix and the pattern of intrauterine edema as monitored with ultrasound. The vaginal portion of the cervix exhibits cyclic changes that reflect the rise and fall of estrogens and progesterone. During estrus, the cervix becomes relaxed and droops toward the ventral floor of the anterior fornix, whereas in diestrus, under the influence of progesterone, the external cervical folds become more rigid and buttonlike, or “tight and white” in the vernacular. One can appreciate these changes by visual examination with a vaginal speculum.

Changes in intrauterine edema are evident, as monitored by ultrasound imaging, in the pattern of fluid (edema) present in the endometrial folds during estrus (Figure 16.1-3). The appearance of edema often is used to indicate estrus, but an important note is that the relationship between edema and ovulation is inverse. Edema is maximal several days before ovulation and then begins to dissipate. Ovulation occurs 3 to 4 days after peak edema scores are exhibited and the edema pattern is in the process of dissipation.[23] Because estrogen stimulates edema rapidly (within 6 hours), the presence of edema appears to be a useful indicator of estrogen secretion. However, dissipation of the edema is an active process, requiring the 1028
presence of ovaries, and likely involves progesterone as well. Far more intriguing then is the question of 1029
the mechanism of dissipation of edema. What is the purpose of edema in the first place if an active process exists for its dissolution before ovulation?

16.1.2.1.4

Hormones

Estrus in mares is characterized by increasing estrogen and a prolonged elevation in LH. The prolonged elevation of LH,[24] often reaching peak concentrations after ovulation, may reflect the need for extensive tissue remodeling of the ovaries for ovulation to occur. Estradiol reaches peak concentrations of greater

than30 to 40 pg/ml 2 to 3 days before ovulation. Evidence exists for a positive feedback effect of estradiol on LH,[25] but evidence also suggests that LH rises spontaneously after corpus luteum regression and the loss of progesterone negative feedback. This raises the question of whether estrogen positive feedback is necessary for the ovulatory increase in LH or whether it merely serves to enhance the default situation of elevated LH in the absence of progesterone.

16.1.2.2 DIESTRUS

Diestrus is essentially the polar opposite of estrus from the behavioral standpoint.

16.1.2.2.1 Behavior

Mares generally exhibit little or no interest in the approach of a stallion, and this often is manifested by violent demonstrations (kicking, switching of the tail, laying the ears flat, vocalizing) in a teasing situation. Rising progesterone concentrations are thought to play a role in the sexual nonreceptivity of mares. Although not critically determined, the sexually negative behavior of mares is assumed widely to be associated with progesterone concentrations greater than 1 ng/ml. Progesterone concentrations increase quickly after ovulation, reaching 1 ng/ml by 24 to 48 hours after ovulation, which coincides with the expected onset of diestrus.

16.1.2.2.2 Ovarian Morphology

The primary feature of ovarian morphology in diestrus is the presence of a corpus luteum within the ovary. Because of the inside-out structure of the ovary, and the restriction of ovulation to the ovulation fossa, the corpus luteum remains almost entirely within the ovary and provides little evidence of its presence by transrectal palpation, unlike ruminants. The advent of ultrasound imaging has improved diagnostic capabilities by enabling practitioners to visualize the corpus luteum.

16.1.2.2.3 Hormones

Diestrus is dominated by elevated progesterone, with its negative feedback effect on LH secretion.

16.1.3 Postpartum Period

Immediately following expulsion of the fetus, the equine uterus begins the process of involution, and this continues for several days after passage of the placenta. During this time, detection of fluid within the uterine lumen by ultrasound is not abnormal. However, the uterine fluid (lochia) and debris should dissipate within 7 to 10 days after parturition in preparation for “foal heat” in the mare.[26] One should not detect fluid by ultrasound 10 to 14 days postpartum, and the uterus should be restored to nearly prepregnancy condition within 3 to 4 weeks.

Foal heat is described as the first period of sexual receptivity following parturition and usually begins 7 to 9 days after foaling.[27] The first ovulation after foaling occurs on average at 9 days after foaling. Depending on the efficiency of uterine involution, the fertility of this foal heat varies. If significant fluid is present within the uterus at foal heat, breeding the mare is not recommended. In addition, studies regarding the effect of season on first postpartum ovulation suggest that mares that foal in January and February tend to have longer intervals

from foaling to the first fertile ovulation than mares that foal in late spring.[28] After the foal heat most mares have a 30-day heat that occurs approximately 21 days after the foal heat and may represent a more fertile estrous cycle.

In addition to the effects of season, a condition known as lactational anestrous may develop immediately after foaling. In some cases the condition may persist until weaning (4 to 6 months). Determining whether the lactational anestrous results from the foal nursing or the time of year (seasonal) is important. Limited studies have been performed in which foals were removed from mares at varying time points after parturition. Research indicates that removal of the foal hastens the onset of estrus. Foal removal has been associated with elevated LH concentrations and increased ovarian follicle diameter.[29]

16.2

16.2—Mare Breeding Soundness Examination

Nigel R. Perkins

The veterinarian may perform a breeding soundness examination of the mare for a variety of reasons, including prepurchase or prebreeding examination of a mareto confirm the absence of detectable abnormalities involving the genital tract and examination of a subfertile mare following unsuccessful breeding or tentative identification of a

potential problem associated with the genital tract. Procedures that one should perform in all breeding soundness examinations include perineal examination, rectal palpation, ultrasonography, vaginoscopy, and digital vaginal examination. One also should consider additional procedures, choosing procedures tailored to the signalment, history, and initial findings of each mare.

16.2.1 Signalment and History

History and signalment represent an important and often overlooked part of the breeding soundness examination. They can identify possible problems and guide the diagnostic approach (Table 16.2-1). Breeding history should include more detailed information from the immediate past, including information on the standard of breeding management and facilities. Obtaining historical information on the entire breeding career of the mare is also valuable, though more difficult. 1030

1031

TABLE 16.2-1 Details of Information to Be Gathered During History Taking

HISTORY	COMMENTS
General health	Vaccination, deworming, foot care, dental care, nutritional history, systemic diseases, management
Athletic	Level of activity; when athletic career ended
Cycling	Length of estrus, expression of estrus, interovulatory interval
Breeding	Number of cycles bred, breeds per cycle, natural or artificial insemination, fertility of stallion; when mare was last bred
Pregnancies	Number of diagnosed pregnancies and outcomes
Foaling	Any history of dystocias; how they were managed
Prior reproductive examinations	Diagnoses, treatment, management
Prior reproductive surgeries	Nature of surgery, date performed and outcome
Drug use during breeding season	Ovulation induction, estrous cycle manipulation

16.2.2 General Physical Examination

General observation of the mare while loose and being led to the stocks allows assessment of behavior and preliminary assessment of condition and conformation. One should perform a brief general physical examination to ensure the mare has no detectable condition that could interfere with her ability to conceive or carry a foal to term. One should inspect the mammary glands visually and with digital palpation for evidence of abnormalities such as mastitis, fibrosis, and neoplasia and should ensure the mare is in good body condition. In general, excessive condition does not interfere with reproductive potential, but poor condition may.

16.2.3 Restraint

One must ensure the mare is restrained adequately before examination. What constitutes adequate restraint depends on the nature of the mare, the skill and experience of the handler and veterinarian, the procedures being performed, and the physical facilities available. One should exercise particular care when performing a breeding soundness examination (BSE) on mares with little prior exposureto procedures such as transrectal palpation. Chemical restraint is an effective and safe method in most cases for BSE procedures, particularly in those procedures that are less well tolerated or more prolonged. Chemical restraint may cause some degree of relaxation of the perineal region and may alter the assessment of vulval conformationin some cases. If possible, one should examine vulval conformation before tranquilizing the mare.

16.2.4 Examination of External Genitalia

One should inspect the perineal region for indications of vulval discharge and gross abnormalities of the anogenital region. Vulval discharge or urine scalding of the inner thighs may suggest genital infection, urine pooling, or urinary incontinence. Clitoral enlargement may indicate prior exposure to androgens or progestagens or an intersex condition.

Normal vulval lips are vertical, have good tone, and are in close apposition. One should part the vulval lips gently to determine if air is readily aspirated into the vagina. If vulval apposition is poor or aspiration of air readily occurs, then the mare may be prone to pneumovagina and at increased risk of ascending vaginitis.

Vulval integrity is important in the formation of an effective seal against contamination of the genital tract with air, urine, feces, and potential pathogens.[1] One should assess vulval conformation by digital palpation adjacent to the vulval lips to locate the caudal bony pelvic brim. Pascoe's description of a Caslick index has been modified to produce a simple assessment technique for vulval conformation[2]:

- VC (vulval conformation) good: No Caslick is required. Dorsal commissure of the vulva is lessthan 4 cm above the bony pelvic brim, and vulvallips are within 10 degrees of vertical and form an effective seal.
- VC marginal: Caslick possibly is required. Dorsal commissure of the vulva is 4 to 7 cm above the bony pelvic brim, and vulval lips are within 10 to 20 degrees of vertical, and vulval lips still form an effective seal.
- VC poor: Caslick or some other corrective procedure definitely is required. Dorsal commissure of vulval is5 to 9 cm or more above the bony pelvic brim, and vulval lips are 30 degrees or more in front of vertical, and vulval seal is less than effective.

16.2.5 Transrectal Palpation and Ultrasound Examination of the Genital Tract

An absolute imperative is confirmation of the nonpregnant status of the mare before performing any procedure that could threaten a pregnancy, even if the history suggests that she is not pregnant.

Transrectal palpation of the genital tract is associated with some risk of rectal mucosal trauma and potentially
laceration. The risk increases if one uses excessive force, if palpation continues in the presence of 1031
pneumorectum, and if the mare strains excessively. Infusion of 50 ml of2% lidocaine into the rectum through a 1032
piece of flexible tubing or added to a small quantity of lubricant, may help ease straining. Administration of 50

to 100 mg propantheline bromide (Propan-B, Vetpharm Ltd, Auckland, New Zealand) by intravenous injection several minutes before the examination also may help prevent straining but may interfere with assessment of uterine tone.

TABLE 16.2-2 Application of Transrectal Palpation and Ultrasound of the Genital Tract for Assessing Various Parameters

ORGAN	STRUCTURE	DETAIL OF ASSESSMENT	TECHNIQUE
Ovary	Ovary	Size, shape, presence of ovulation fossa	Palpation (P), ultrasound (US)
		Echotexture of contents	US
		Consistency of tissue	P
	Corpus hemorrhagicum	Presence	P, US
	Corpus luteum	Presence/absence, size, shape, echotexture	US
	Follicles	Size	P, US
		Shape, wall thickness, echotexture; echotexture of contents	US
		Turgidity	P
	Uterus	Diameter, shape, tone, wall thickness, endometrial folds, luminal fluid (larger amounts)	P, US
		Wall echotexture, endometrial folds, luminal fluid volume, echotexture	US
	Cervix	Length, width, depth	P, US
		Echotexture	US
		Relaxation	P
Vagina and vestibule		Fluid accumulation	P, US

One should take a methodic approach to palpation of the genital tract. The author normally locates the uterus and palpates structures in the following sequence: right uterine horn, right ovary, right uterine horn, left uterine horn, left ovary, left uterine horn, uterine body, and cervix.

One assesses cervical size and consistency by pressing the cervix down against the pelvic floor. One can measure cervical relaxation most effectively on a sliding scale from 0% relaxed (tightly closed, tubular cervix) to 100% relaxed (indistinguishable from adjacent uterus).[3]

Purposeful assessment of anatomic structures other than the genital tract as part of the palpation examination, including pelvis, intestines, lymph nodes, and bladder, is important. One should note the presence of soft tissue or bony changes that may narrow the luminal diameter of the pelvis. Possible causes include vaginal lacerations, hematoma, abscessation, neoplasia, and pelvic fracture.

One uses the same basic approach for ultrasound examination. While holding a linear transrectal ultrasound probe, one can extend the fingertips beyond the ventral surface of the probe to assist in locating genital tract structures and to palpate uterine horns to assess uterine tone. One initially identifies the uterine body as a landmark by sweeping the probe from side to side in the anterior pelvis. One then follows the uterine body cranially to the bifurcation and sweeps the probe out toward the right uterine horn and right ovary. One examines the structures in the same order as for palpation. As one withdraws the probe into the pelvic cavity, one examines the uterine body by moving the probe from side to side.

One should use a simple recording system and should note the uterine horn diameter about one third of the distance from the uterine body. One also should note uterine tone, along with presence of dilations and fluid. One can assess endometrial folds by gently palpating the uterus between fingers and thumb and can assess dimensions and shape of each ovary to ensure that the ovulation fossa is detectable (loss of ovulation fossa can be an early indicator of distortion of the normal ovarian shape caused by neoplasia). One records all follicles larger than 15 mm in diameter individually, records smaller follicles as multiple small follicles, and records loss of turgidity for preovulatory follicles (softness being a possible indicator of impending ovulation). One should consider ultrasound examination to be a routine part of a reproductive tract examination. Ultrasound examination allows the use of electronic callipers for measuring structures and allows assessment of tissue and fluid characteristics. Table 16.2-2 gives comparative information on the application of palpation and ultrasound for assessing various genital tract structures.

16.2.6 Evaluation of the Ovaries

One should suspect abnormal ovarian enlargement if an ovary is greater than 10 cm in diameter and when one cannot attribute the increased size to recent ovulationor a follicle and enlargement persists for more than a month.[3,4] Although an enlarged ovary may be associated with pathologic processes (neoplasia,[5,6] abscess), 1032
more often enlargement has physiologic causes (persistent follicles,[7] hematoma, multiple corpora lutea). Small and inactive ovaries may follow seasonal anestrus, reproductive senescence in old mares, pituitary gland dysfunction, severe malnutrition, administration of anabolic steroids, or congenital infertility caused by sex chromosome abnormalities.[8] Sex chromosome abnormalities often are associated with hypoplasia or segmental aplasia of the tubular tract. Karyotyping may be useful to investigate such mares further. Chromosomal abnormalities alsohave been reported from subfertile mares that have foaled previously and have no detectable abnormalities of the genital tract. With this in mind, one may consider karyotyping in mares for which routine diagnostic procedures fail to explain subfertility. Diagnosis and treatment of specific ovarian disorders are discussed elsewhere in this chapter. 1033

16.2.7 Evaluation of the Uterus

Ultrasonography is useful for evaluating presence, quantity, and echotexture of uterine luminal fluid. Fluid echotexture correlates with the amount of debris or white blood cell infiltration into the fluid. Table 16.2-3 shows a grading system for recording uterine fluid echotexture.[9] As a result, the presence of an amount of grade I, II, or III fluid during any stage of the cycle indicates endometritis. Table 16.2-4 shows a grading system for recording the volume of intrauterine fluid.

Complete absence of detectable uterine luminal fluid during estrus is associated with absence of cytologic inflammation in 99% of cases.[10] Small or minute volumes of clear fluid during estrus are likely to be normal, particularlyif present during early estrus before complete cervical relaxation and maximal uterine drainage.

Large volumes of clear fluid during estrus, fluid that persists into late estrus, or smaller volumes during early diestrus suggest an increased predisposition to endometritis and reduced pregnancy rates compared with mares without fluid.[10,11] Luminal fluid visible more than 12 to 20 hours after breeding indicates mating-induced endometritis.[12,13] This condition recently has been reported in 10% to 15% of mares being bred on a commercial Thoroughbred stud.[14]

TABLE 16.2-3 Grading System for Recording Volume of Intrauterine Fluid

CLASSIFICATION	MAXIMUM FLUID DEPTH (mm)	GROSS DESCRIPTION
VS (very small)	1 to 2	Barely detectable
S (small)	1 to 5	Often focal
M (moderate)	5 to 20	Obvious fluid
L (large)	>20	Immediately apparent

TABLE 16.2-4 Classification System for Recording Uterine Fluid Echotexture

GRADE	ULTRASOUND APPEARANCE	GROSS APPEARANCE
I	White (hyperechoic)	Thick and creamy
II	Light grey	Milky
III	Black with white specks	Obvious sediment in fluid
IV	Black (anechoic)	Clear fluid

Discrete hyperechogenic reflections in the uterine lumen on ultrasonographic examination indicate air. Pneumouterus may be visible in normal mares soon after uterine treatment, insemination or breeding but should not be visible more than 48 hours after breeding or treatment. The presence of pneumouterus at times other than soon after breeding or uterine therapy indicates loss of integrity of physical barriers to contamination (vulva, vestibulovaginal sphincter, and cervix). Endometritis is discussed in detail later in this chapter.

Circumscribed, discrete collections of clear fluid within the uterine lumen indicate endometrial cysts or a conceptus. Cysts may occur on the endometrial surface or within the endometrium. Cysts may be single, discrete structures closely resembling a conceptus, or complex, compartmentalized structures with irregular borders. Cysts that protrude into or occlude the uterine lumen may reduce fertility by interfering with embryo mobility and maternal recognition of pregnancy.[15–17] Cysts within the endometrium may interfere with gland function.

Properties of an early conceptus that one can use to distinguish it from a cyst include movement between days 10 to 16 after ovulation, spherical symmetric appearance, rate of growth (cysts assumed to grow little if at all), and appearance of the embryo proper after about day 20. In addition, palpable changes in the tract occur that are consistent with early pregnancy (increased uterine tone and closed, elongated cervix) and that would not be expected to occur in a nonpregnant mare with endometrial or lymphatic cysts. Any association between cystsand reduced fertility remains unclear.[18] Large cysts or large numbers of cysts may interfere with embryonic movement, maternal recognition of pregnancy, and early placentation. Extensive glandular cystic

change also may affect uterine gland function adversely and compromise establishment or normal development in pregnancy.

Pyometra is a chronic condition with mucoid or mucopurulent material within the uterine lumen, withor without cervical occlusion. The condition does not depend on the presence of a corpus luteum as it usually does in other 1033
species and typically does not result in any systemic signs of illness. One may mistake pyometra for pregnancy 1034
on palpation because of fluid distention of the uterus, but one cannot diagnose the condition effectively with ultrasound.[19]

Adhesions and scarring involving the endometrium may result from infusion of irritating solutions into the uterus and perhaps from trauma associated with dystocia and its correction. Luminal adhesions involving the cervix have similar initiating causes. The role of chronic endometritis or iatrogenic causes such as mechanical curettage in uterine or cervical adhesions is less clear. Adhesions may reduce fertility, for example, by interfering with function of the uterotubal junction or with embryo movement and maternal recognition of pregnancy.[16]

Occlusive adhesions may result in accumulation of fluid in the proximal portions of the tubular tract, and one may detect this on palpation or ultrasound examination of the tract. More commonly, one detects adhesions during hysteroscopy.

Focal uterine lesions may respond well to surgical removal using a biopsy instrument or laser surgical equipment guided by hysteroscopy. If lesions are extensive or involve the deeper layers of the endometrium, then the prognosis may be poor and treatment may not be warranted. Cervical adhesions commonly are managed by manual disruption and then repeated application of topical ointment containing an antibiotic and a steroid in an attempt to prevent recurrence. In many cases, cervical adhesions tend to recur once treatment stops.

Ventral sacculation is associated with a loss of normal muscular contractile activity in the uterine wall with the uterine wall forming sacculations ventrally at the baseof one or both uterine horns. The condition is more common in older, multiparous mares and may indicate increased risk of endometritis caused by loss of the normal contractile mechanisms responsible for expelling uterine luminal fluid.

16.2.8 Intravaginal Procedures

16.2.8.1 HYGIENE

Good hygienic practice is essential in performing any vaginal procedure and particularly those procedures that involve penetration of the cervix. Hygiene is perhaps the simplest and most fundamental principle of good reproductive practice. One should bandage the proximal portion of the tail or enclose it in a plastic sleeve and tie it to the neck of the mare with a quick release knot or should have an assistant hold the tail out of the way. One then washes the perineal region with water and detergent and rinses thoroughly, preferably with a spray nozzle attached to a hose to deliver a constant supply of fresh clean water. One wipes just inside the vulval lips with damp cotton to remove any contaminating material; this is particularly important for mares with sloping vulval lips or if one has just performed a rectal examination.

Use of sterile, plastic sleeves for vaginal procedures is ideal. A practical alternative the author uses is to maintain a zip-lock bag of clean, plastic sleeves in a dust-free area to be used for vaginal procedures only.

One should use sterile lubricant and sterile equipment and should be meticulous about avoiding contamination of equipment or sleeves/gloves during any procedure.

16.2.8.2 VAGINAL SPECULUM EXAMINATION

One inserts a sterile, lubricated speculum into the vestibule in a slightly dorsal direction to avoid the urethral opening and pushes the speculum throughthe vulvovestibular sphincter, assessing sphincter integrity on insertion of the speculum. Single use, sterile, disposable specula are preferrable to a metal Caslick speculum for routine examinations because they reduce the risk of iatrogenic infection. In some cases, a self-retaining metal Caslick speculum may provide better visualization of the caudal vagina and vestibule.

Vaginoscopy is useful for detecting vaginal hyperemia, suppurative exudates, persistent hymen, urine pooling, varicose veins, vaginal trauma, rectovaginal defects, and cervical defects. Although one may perform vaginal speculum examination at any stage of the cycle, inspection of mares suspected of pooling urine is performed best during estrus because estrogenic relaxation of the genital tract and perineal region is maximal at this time.[20] Vaginal speculum examination is an important component of the breeding soundness examination but should not be considered a routine procedure to be performed repeatedly in normal mares. Repeated vaginoscopy may be associated with increased risk of iatrogenic vaginitis and persistent infection. As a result, the author prefers to assess cervical relaxation routinely by transrectal palpation.

16.2.8.3 MANUAL EXAMINATION OF THE VAGINAAND CERVIX

Examination of the genital tract is incomplete without manual exploration of the vagina and cervix. The major benefit in this procedure is detection of cervical defects. Once one inserts the hand into the anterior vagina, one places the forefinger into the cervical lumen and the thumb in the vaginal fornix. One then rotates the hand and palpates the entire circumference of the cervix between finger and thumb to feel for disruption in the cervix caused by lacerations or damage to submucosal layers that might interfere with the ability of the cervix to close effectively. Cervical disruption is only significant if it prevents the cervix from forming an effective seal during diestrus and pregnancy. A partial tear involving the external os of the cervix 1034
may not require treatment if the cervix can maintain an effective seal. For this reason, one should assess the 1035
severity of cervical disruption when the mare is in diestrus.[21]

One should take care while performing a manual examination of the vagina and cervix to palpate thevaginal surface for problems such as rectovaginal fistulae, vaginal lacerations, and perivaginal hematoma or abscess formation.

16.2.8.4 CULTURE OF THE UTERINE SECRETIONS AND ENDOMETRIAL CYTOLOGIC EXAMINATION

One should not perform any procedure that involves penetrating the cervix of a mare until one has confirmed the nonpregnant status of the mare by transrectal palpation alone or along with ultrasonography.

A variety of instruments and techniques have been described for culturing the genital tract. The lack of consistency in methodology almost certainly has contributed to the lack of consensus regarding the role and interpretation of genital tract cultures.

One may take culture samples from multiple sites within the genital tract, including endometrium, cervix, vagina, clitoral fossa, and clitoral sinuses. One should take samples for genital tract culture to investigate possible endometritis or as part of a BSE from the endometrial lumen and not from the vagina or cervix. One should take an endometrial culture sample before any other invasive procedure in a BSE to avoid the risk of inadvertent contamination of the uterine lumen before taking the sample. One should use a guarded culture rod to minimize the risk of contamination with material from sites other than the uterine lumen,[22] and one may use single- or double-guarded culture rods. Taking an endometrial culture from a uterine biopsy sample is also possible as long as one takes the culture sample in a sterile manner and before placing the tissue into fixative. Consensus is lacking on the optimal time of the cycle for taking endometrial culture and cytologic samples. Some support exists for performing endometrial cultures on the first or second day of estrus when uterine secretions are increasing and the flushing action of the uterus is just beginning.[23,24] Mares with endometritis have been reported to accumulate free luminal fluid in late diestrus, and this represents an alternative time for endometrial culture.[25]

One should carry the guarded culture rod into the vagina and through the cervix beside one finger and then pass it cranial to the finger into the endometrial lumen, pushing the culture tip through the guard and rolling it against the endometrial surface for 30 to 60 seconds. One withdraws the culture tip into the rod before withdrawing the culture rod to avoid contamination during removal from the genital tract.

One should transfer the sample onto final growing medium immediately after completing the culture to allow quantification of colony numbers as an indication of severity of infection. Where possible, colony growth should be quantified because heavy growth after 24to 48 hours of incubation is more meaningful than afew scattered colonies. If immediate plating is not possible, one should transfer the culture tip in a sterile manner into appropriate transport medium to transport the sample to a laboratory. Use of transport medium allows proliferation of some species and possibly reduces growth of others, so colony counts are no longer interpretable.

Interpretation of endometrial culture results is difficult. False-positive and false-negative results are common. Several recommendations to minimize the likelihoodof an erroneous interpretation follow. One should interpret culture results along with results of concurrent endometrial cytologic examination. In addition, one should consider whether the organisms recovered represent pure or mixed growth and whether growth is heavy or light. Further work is required on technique and interpretation for endometrial cultures. For example, recovery of organisms in pure culture traditionally has been given more meaning than recovery from mixed cultures. However, recent evidence suggests more cases of acute endometritis are associated with mixed bacterial growth on culture than pure growth.[26]

A wide range of organisms have been isolated from acute cases of endometritis. A combination of positive culture and inflammation on endometrial cytologic examination is sufficient to diagnose endometritis and identify the organism(s) recovered as the causative agent(s). A positive bacterial culture in the absence of any cytologic evidence of inflammation is considered likely to be caused by contamination during the culture procedure and does not indicate endometritis.

In the absence of cytologic findings, interpretationof culture results is difficult. Recovery of pure or heavy cultures of the following organisms may indicate endometritis: β-hemolytic streptococci, hemolytic *Esherichia coli*, *Pseudomonas* spp., *Klebsiella* spp., and *Candida* spp.[27,28] One should view recovery of other organisms without concurrent cytologic information with more suspicion.

Some practitioners use endometrial cytologic examination as a rapid screening test to detect endometrial inflammation in mares at the beginning of the breeding season or before breeding. Numerous techniques have been described for collecting cytologic samples. The approach used by the author is simple, rapid, and feasible in busy clinical practice. One uses a guarded culture rod with a snap-on cap (Kalayjian, Kalayjian Industries Inc., Long Beach, California) to collect a culture sample. One withdraws the swab tip into the sheath and rolls the rod against the endometrium to collect fluid and cells inthe cap. After withdrawing the 1035
rod from the mare, one can cut off the cap and tap it against a slide to make the smear from the small drop of 1036
fluid.[29] The smear is dried and stained using any commercial staining kit; for example, Diff-Quik (American Scientific Products, McGaw Park, Illinois). If no endometrial cells are visible on an initial inspection of the slide, one may not have collected the sample from the uterus and one should take another sample. Researchers agree that the presence of polymorphonuclear leukocytes (PMNs) indicates bacterial endometritis, but less consensus exists on the most appropriate methodology for quantifying PMNs. Suggestions are that more than 1 to 2 PMNs in five high-power microscope fields (400×) and more than 1 PMN per 10 endometrial cells in more than one area of the slide may be significant.[30,31] In most cases of inflammation, large numbers of PMNs exist and the diagnosis is obviousand rapid.

16.2.8.5 ENDOMETRIAL BIOPSY

Preparation for endometrial biopsy is the same as for culture or cytologic examination. Diestral samples are generally preferable to estral samples because physiologic changes in the endometrium during estrus make the slides more difficult to interpret. However, one may take samples at any stage of the cycle as long as the information on the stage of cycle is provided and the person reading the slide is experienced at assessing equine biopsy slides. In the absence of clinically detectable pathologic findings involving the uterus, a single endometrial biopsy sample is representative of the entire endometrium.[32]

One introduces the sterile, mare biopsy instrument into the uterine lumen and guides it by one hand placed in the vagina. The traditional technique then involves withdrawing the hand from the vagina and inserting it into the rectum. One then can direct the instrumentto a specific site within the uterus, generally the base of one horn. One then turns the instrument on its sideand the gently opens the jaws. One presses a portion of endometrium between the jaws using the index finger within the rectum and closes the jaws to remove the tissue sample. A simpler vaginal technique is useful for collecting biopsy samples and does not require a sample from a specific site.[33] One introduces the instrument into the uterine lumen and leaves the hand in the vagina withthe index finger in the cervical lumen. One advances thetip of the instrument about 2 to 3 cm into the uterine lumen with the jaws closed, opens the jaws, and advances the instrument another 1 to 2 cm. One then can deviate the instrument slightly to one side and close the jawsto collect a sample. Using this approach, one takes the sample from the cranial uterine body close to the bifurcation. This approach has the advantage of being quick and simple and allows the operator to return for a second sample immediately if the first sample is too small, whereas the rectovaginal technique often results in gross contamination of the instrument and vulva during the procedure so that a second sample is often not possible unless the mare is cleaned again and a second sterile instrument is available.

One removes the specimen from the biopsy basket using a small-gauge needle and transfers it to fixative solution, preferably Bouin's fixative or alternatively 10% buffered formalin. One should transfer samples placed into Bouin's solution to 10% formalin or 80% ethanol after 12 to 24 hours for optimal retention of cell detail and tissue integrity.[34] Interpretation of endometrial biopsy results based on the Kenny system is discussed later in this chapter.[35–37] Endometrial fibrosis is a permanent, degenerative change occurring

around glands (fibrotic nests) or gland branches and also adjacent to the basement membrane of the luminal epithelium. Fibrosis often forms in concentric layers around gland branches or glands, and the number of layers of fibrosis is related to the severity of the degenerative change.[35] Paired biopsy samples, taken at the initial diagnostic workup and again 4 weeks after completion of uterine therapy, appear to improve the usefulness of an endometrial biopsy as a prognostic indicator of fertility in a mare. In one study, mares classified as grade III before treatment that improved to grade II after treatment achieved a foaling rate of 40%, whereas mares that were still grade III after treatment did not foal. Any improvement is likely to be in reversible pathologic changes such as inflammation. Fibrotic changes are irreversible.[38]

16.2.8.6 UTERINE ENDOSCOPIC EXAMINATION: HYSTEROSCOPY

Hysteroscopy allows direct visual inspection of the uterine lumen through a flexible fiberoptic endoscope. Hysteroscopy is indicated when other diagnostic procedures do not detect a cause for subfertility or for further examination of a mare with a suspected uterine luminal lesion.[39,40]

Tranquilization is a useful restraint aid, for the procedure is associated with a mild level of discomfort. One prepares the perineum as for other vaginal or uterine procedures. If the endoscope is sterilized by immersion in chemicals, rinsing with sterile water is essential, especially of the biopsy channel. Failure to rinse the equipment adequately could result in deposition of irritant chemicals into the uterine lumen. One carries the sterilized endoscope into the vagina, manipulates it through the cervix, and then advances it into the uterus. One occludes the cervical lumen by inserting one or two fingers alongside the endoscope or by gently holdingthe external os of the cervix around the endoscope. One distends the uterine lumen with saline or
water infused through a flexible catheter held adjacent to the endoscope or with air delivered through the 1036
endoscope. One should assess endometrial folds while the uterus is being distended because they flatten out 1037
and become difficult to distinguish in the fully distended uterus. One then manipulates the endoscope up each uterine horn, allowing visualization of the entire endometrial surface up tothe horn tip where the oviductal papilla should be. Hysteroscopy allows direct visualization of a variety of abnormal changes, including inflammation, polyps or neoplasia, cysts, adhesions, and severe scarring or fibrotic change. Hysteroscopy also can aid treatment of a number of conditions, including guided retrieval of foreign bodies and laser surgical management of conditions such as endometrial cysts or adhesions.

Excessive distention of the uterus may cause discomfort and elevated heart rate and should be avoided.[41] Mares subjected to hysteroscopy appear to be at risk of developing endometritis subsequently and examining the mare during the subsequent estrus period may be advantageous to check for evidence of endometritis.

16.2.9 Hormonal Assays

In the nonpregnant mare, one may collect serum or plasma samples to measure a variety of reproductive hormone concentrations including progesterone, estrogens, testosterone, inhibin, and gonadotropins. Other conditions that may have effects on cyclicity and fertility include abnormalities involving the thyroid and adrenal glands and pituitary gland neoplasia.

The ovarian luteal tissue produces progesterone. Serum progesterone concentrations are low during estrus and begin to rise within 12 to 24 hours after ovulation, peaking between days 5 to 10 after ovulation.[42] One can use progesterone assays in nonpregnant mares to assistin determining the stage of the cycle and to confirm that ovulation has occurred. One also can use the assays as an indirect method of pregnancy diagnosis, but false positives are common. Progesterone is necessary for pregnancy maintenance, and primary luteal insufficiency

has been linked with pregnancy loss. Support for this association comes from anecdotal descriptions of mares maintaining pregnancy while on progesterone supplementation despite previous histories of pregnancy loss. Authors have recommended that progesterone concentration in peripheral blood of pregnant mares be greater than2.5 to 4 ng/ml for normal pregnancy maintenance.[43] However, no evidence indicates that primary luteal insufficiency is an important cause of pregnancy loss. Single samples of peripheral blood concentrations are difficult to interpret because repeated sampling of normal pregnant mares has shown that blood levels vary widely over short periods of time.[44]

Thyroid gland dysfunction has been linked to subfertility in mares. Thyroidectomy of pony mares was not shownto have any adverse effect on reproductive performance, and the diagnosis of thyroid gland dysfunction as the cause of poor reproductive function remains controversial.[45] Horses with pituitary gland hypertrophy or hyperplasia (Equine Cushing's like disease), typically exhibit variable degrees of hirsuitism with a range of other systemic signs.[46] Diagnosis and treatment of this disorder is discussed in detail elsewhere in this text.

Ovarian neoplasia, particularly granulosa theca cell tumors, may be associated with increased production of testosterone and inhibin by the affected ovary. Serum inhibin concentration is elevated in approximately90% of mares with a granulosa theca cell tumor, and testosterone is elevated in about 50% to 60% of cases.[47] Horses with functional granulosa theca cell tumors almost invariably have a nonfunctional contralateral ovary and are anovulatory. Therefore a serum sample demonstrating elevation in inhibin or testosterone and low progesterone concentrations is consistent with ovarian neoplasia. Normal ranges in nonpregnant mares for inhibin and testosterone are 0.1 to 0.7 ng/ml and less than45 pg/ml, respectively.[6,47]

Measurement of estrogen concentration in blood, urine, feces, milk, and saliva has been used for monitoring the cycle,[48] determining pregnancy status,[49–51] and monitoring fetal viability.[52] Peripheral blood estrogens may be unconjugated or conjugated (bound to sulfates), and different forms of estrogens are found in the mare, particularly during pregnancy. Conjugated estrogens generally exist in the circulation at much higher concentrations than unconjugated forms, and measuring estrone sulfate or total conjugated estrogens appears to offerthe most use for the indications mentioned previously. A dramatic rise in peripheral blood estrone sulfate concentrations occurs in pregnant mares after day 60 of pregnancy, whereas in fecal assays this rise may take up to 150 days to occur.[53,54] A rapid decline of estrone sulfate concentration in a pregnant mare may be an indication of loss of fetal viability.[52]

Monitoring serum or plasma concentrations of gonadotropin-releasing hormone, gonadotropins (follicle-stimulating hormone and luteinizing hormone), and steroids appears to offer promise in the diagnostic assessment of the hypothalamic-pituitary-ovarian axis. Measuring these products appears to offer considerable future potential, but additional research and development are required before such assays can offer value to field practitioners. Currently, little information is availableon the existence of abnormalities in the hypothalamic-pituitary-ovarian axis, their potential relationship to subfertility, or their detection by measurement of various hormone concentrations. Practical difficulties exist in assessing the production and release of gonadotropin-releasing hormone or follicle-stimulating hormone and luteinizing hormone, because 1037
assessment may require cannulation of the pituitary venous sinuses.[55] In addition, these hormones are released 1038
in a pulsatile manner, with pulse frequency and amplitude influencing their ultimate effect.[56] Finally, varying isoforms of these hormones exist, each with a differing bioactivity that may be difficult to distinguish on enzyme-linked immunosorbent assay or radioimmunoassay.[57] Currently, measurement of these and other central nervous system hormones appears to be restricted to researchers.

16.3 16.3—Mare Reproductive Pathology

Carlos R.F. Pinto

Dale L. Paccamonti

16.3.1 Vulva

The integrity of the vulvar lips and their anatomic relation to the perineal area and anus are an essential component of the fertility of a mare because they provide the first barrier to contamination between the external environment and the uterus. The endocrine patterns associated with each stage of the estrous cycle and pregnancy can influence the disposition of the vulva, affecting vulvar length and tone. In general, the vulva should have at least two thirds of its length below the pelvic brim, the slope of the vulva in relation to the vertical axis should not be greater than 10 degrees, and the vulvar lips should have an even and firm apposition. Absence (natural or acquired) of a normal perineal conformation can facilitate the entry of air (pneumovagina), feces, and potential pathogens into the reproductive tract, which jeopardizes the fertility of the mare.

16.3.1.1 BODY WEIGHT

Severe loss of body condition, as experienced by some pregnant mares not adequately supplemented during the winter, results in a sunken anus and an increased slopeof the vulva. An apparently normal perineal conformation noted in mares in good body condition may become less than adequate if loss of body weight is extreme. Contamination of the vagina with feces during mid to late gestation may lead to ascending bacterial placentitis, one of the leading causes of abortion and neonatal septicemia in the United States.[1]

16.3.1.2 PARITY AND AGE

Aging of the mare associated with repeated foaling can cause stretching and loss of tone of the perineal muscles that provide the ability of the vulva to form a barrier to external contamination and entry of air into the vagina. Injury to the mare during foaling also aggravates this condition, resulting in loss of vulvar tone and apposition of the labia. Mares undergoing episiotomy also may have permanent damage to vulvar structures.

16.3.1.3 CASLICK VULVOPLASTY

Surgical closure of the dorsal part of the vulvar labiais intended to correct poor perineal conformation. By decreasing the length of the vulvar cleft, one decreases entry of air and potential pathogens into the vagina 1039
ina mare otherwise susceptible to pneumovagina, fecal contamination, and associated complications. This 1040
procedure, however, is overused in mares in which such intervention is not warranted. Paradoxically, a mare with successive Caslick surgeries can experience considerable loss of vulvar tissue, thus generating an abnormal perineal conformation.

Another indirect complication associated with the Caslick vulvoplasty is the increased incidence of vulvar lacerations and dystocias in mares in which the vulva was not opened before foaling. Regardless of the originating cause, Caslick operation is used to correct first-degree perineal laceration affecting only the perineal skin and vulvar mucosa. Second-degree (laceration of deeper tissues of the perineal body) and third-

degree (a defect resulting in communication of the ventral rectumwith the dorsal vagina) lacerations require more elaborate reconstructive surgery to correct.[2] As a rule, one should delay any corrective surgery of the perineal body and vulva until inflammation and edema of the involved tissues has resolved. Mares with third-degree rectovestibular laceration invariably develop endometritis, but endometrial biopsy of mares affected with third-degree laceration have shown a rapid endometrial response to the surgical repair of the laceration; mares then can be artificially inseminated by 2 weeks after surgery.[3]

16.3.1.4

EQUINE COITAL EXANTHEMA

Equine coital exanthema is a venereal disease caused by equine herpesvirus type 3. Mares infected with equine coital exanthema develop pustules and ulcers in the vulvar mucosa and perineal area. Once the lesions start to heal (usually by 14 days after the onset of clinical signs), characteristic depigmented areas in the vulvar labia and perineal skin are visible.[4] Similarly to other herpesvirus-induced diseases, lifelong infection is the rule. Recrudescence after stimuli such as stress, systemic disease, or trauma to the genital area can occur. No specific treatment other than disinfection of pustules and ulcers to prevent secondary bacterial infections during the acute phase is recommended. Natural service should be avoided while active lesions are present to prevent transmission of the disease. One can artificially inseminate affected mares during the symptomatic stage of the disease or wait for 6 weeks after complete healing of equine coital exanthema–associated lesions before natural service.

16.3.1.5

NEOPLASIA

Melanoma is the most common disease affecting the vulva, affecting 80% to 100% of adult gray horses, and less frequently, aging horses of other colors. Common sites for melanoma include the anus, perineum, and vulva. No effective treatment is available for treating melanomas; however, oral treatment with cimetidine (a histamine$_2$ antagonist) has been reported with variable success to result in partial or complete regression of melanocytic nodules.[5] Occurrence of squamous cell carcinoma is less common than melanomas.

16.3.1.6

CLITORIS

The clitoris is enclosed in the clitoral fossa in the ventral part of the vulva but is rhythmically exposed following urination or teasing (winking) as a result of contractions of the vulvar constrictor muscle. The clitoris has several sinuses in which are found a natural smegma. Whereas the lateral sinuses are shallow, the median sinuses are deep enough to allow the growth of bacteria. The anatomy of the clitoris in the mare has become particularly important because the clitoris is an important reservoir for the bacterium *Taylorella equigenitalis* in mares affected with contagious equine metritis. The disease is highly contagious, and the organism can be harboredin the clitoral fossa and sinuses (especially the median sinuses) for prolonged periods. To test a mare for contagious equine metritis, one should swab the median clitoral sinuses and then seed an Amies charcoal medium to be transported (kept preferably at 4° C) to a diagnostic laboratory.

Even in contagious equine metritis–free areas, one must keep in mind that the clitoral sinuses may function as nidi for uterine infection, especially infection iatrogenically induced during diagnostic procedures of the reproductive tract or artificial insemination. Careful asepsis of the perineal and vulvar area, including the clitoral fossa, with a mild disinfectant before any invasive procedures are performed minimizes the risk of introducing potential pathogens into the uterus.

Congenital anomalies of the external genitalia occur in intersex animals that may have underdeveloped vulvar labia associated with an abnormally enlarged clitoris. Treating prepubertal mares with anabolic steroids may lead to enlargement of the clitoris, resulting in a partially and permanently exteriorized clitoris.

16.3.2 Vagina

The vestibule is the area that separates the vulva and clitoris from the vagina proper. At the cranial border of the vestibule, where it meets the vagina, lies the vaginovestibular fold. This folded mucous membrane actsas the second and most important[6] physical barrier between the uterus and the external environment. In young horses, the hymen is usually a weak membranous extension of the vaginovestibular fold. Occasionally, a persistent 1040
hymen may be present in a maiden mare. Usually, a manual examination of the vagina is enough to rupture the 1041
persistent hymen. Some mares with a persistent hymen may accumulate fluid in the vagina proper and uterus (mucometra). Once the persistent hymen is disrupted, evacuation of the fluid is uneventful.

16.3.2.1 PNEUMOVAGINA

Listening for an inrush of air into the vagina when one gently parts the vulvar labia can test the adequacy ofthe vaginovestibular fold as a physical barrier to external contaminants. A positive test (noticeable sound of air rushing in to the vagina) indicates that the vestibular fold is not properly restricting the vagina proper from the outside environment.

Improper functioning of the first barrier (vulva) and second barrier (vaginovestibular fold) may lead to the constant or frequent entry of air into the vagina. The condition can be exacerbated during estrus, when the perineal body is more relaxed than in other stagesof the estrous cycle. Accumulation of small amounts ofa frothy fluid in the cranial vagina may indicate pneumovagina, as may the presence of air in the uterus (pneumouterus) that is visible as hyperechoic particles between the endometrial folds during ultrasonographic examination.

In mares with severe alteration of the perineal conformation, vulvar closure using Caslick vulvoplasty may not correct the problem, and surgical reconstruction of the perineal body (perineoplasty) is recommended.

16.3.2.2 UROVAGINA

This condition, also known as vesicovaginal reflux or urine pooling, refers to the presence of urine in the cranial vagina and possibly in the uterus. As with pneumovagina, mares with marginal perineal conformation may be predisposed to accumulate urine in the vagina during estrus when reproductive organs and the perineal body are relaxed. In older mares with splanchnoptosis, the reflux of urine into the genital tract may be permanent. Urovagina can cause vaginitis, cervicitis, and endometritis, which ultimately result in infertility. Perineoplasty and urethral extension are common surgical procedures to correct this condition.

16.3.2.3 VARICOSE VEINS

During estrus and especially during pregnancy, varicose veins may develop in older mares. Varicose veins can be present in any part of the vagina; however, they often are found in the vaginovestibular area. Bleeding may occur after natural service or spontaneously during mid to late gestation. Occasionally, a persistent

hemorrhage results in considerable blood loss; however, the condition usually subsides with the end of pregnancy. Cautery or ligation of varicose veins is warranted if hemorrhage is persistent or frequent.

16.3.2.4

NEOPLASIA

Vaginal neoplasms are not common in mares. Leiomyomas and squamous cell carcinoma have been reported.

16.3.2.5

VAGINITIS

Minor tears, lacerations, and hematomas are common findings in the vagina of mares after foaling. Medical treatment generally is not needed, and most mares do not show complications in the postpartum period. If more serious trauma occurs, the mare may develop vaginitis. Mares with extensive vaginitis or with a large hematoma may show signs of pain and refuse to stand quietlyto nurse the foal. Vaginal abscesses can develop when a vaginal laceration becomes infected. Clinical signs caused by swelling from a hematoma or abscess include stranguria and straining to defecate. Treatment with antibiotics and antiinflammatory drugs is warranted when one finds extensive vaginitis or abscesses in the vagina. An abscess impinging on the urethra or interfering with defecation may require drainage. Occasionally, vaginal trauma may result in adhesions that can interfere with uterine drainage.

16.3.2.6

RECTOVAGINAL FISTULAE

During parturition, the foot of the foal may be directed toward the dorsal vagina/ventral rectum and if unattended may cause a third-degree perineal laceration. However, if the dystocia is corrected in time, the damage may be limited to a first- or second-degree rectovaginal tear or rectovaginal fistula. Surgical correction of the anatomic defect is necessary to restore fertility.

16.3.2.7

BREEDING TRAUMA

Vaginal lacerations may occur during natural service when the stallion size is disproportional to the mare. Based on the location of the tear in relation to the peritoneal reflection, a vaginal tear may communicate with the peritoneal cavity, likely resulting in peritonitis, or may be retroperitoneal. Treatment includes broad-spectrum antibiotics, antiinflammatory drugs, and tetanus prophylaxis. Peritoneal lavage may be beneficial if the tear communicates with the peritoneal cavity. A breeding roll positioned under the tail of the mare and dorsal to the penis of the stallion prevents the stallion from introducing the penis its full length into the vagina and consequently helps to prevent mating-induced trauma.

16.3.3

Cervix

The cervix is the last of the three physical barriers protecting the uterus from the external environment. Cyclic hormonal changes dictate the tonicity of the cervix. During estrus, the cervix is relaxed and open. High 1041
concentrations of progesterone during diestrus or pregnancy cause the cervix to be tubular, firm, and tightly 1042
closed. These changes are readily palpable per rectum. Moreover, a vaginal examination during estrus reveals the cervix positioned low in the cranial vagina and relaxed, easily dilated, and allowing access to the uterus. During diestrus or pregnancy, a vaginal examination reveals a tightly closed cervical os, pale and positioned high up off the floor of the vagina.

16.3.3.1 CERVICITIS

Inflammation of the cervix often accompanies vaginitis or endometritis. Cervicitis occurs most commonly in the postpartum period, especially after a dystocia. Severe cervicitis associated with metritis also may occur in mares infected with organisms such as *T. equigenitalis* that cause copious purulent discharge.[7] Infusion of certain chemicals such as chlorhexidine or strong iodine solutions into the uterus to treat endometritis may irritate not only the endometrium but also the cervix and vaginal mucosa. If one intends to use such solutions, vaginal speculum examinations between treatments to assess the condition of the cervix are warranted.

16.3.3.2 TRAUMA

Although cervical lacerations may occur during natural service, these lesions are usually small and resolve without major consequences. Occasionally, maiden maresare found in estrus with a tightly closed cervix, which may suffer laceration during natural service, especially if the stallion is disproportionately larger than the mare. However, these tears are usually small and heal without further treatment. Most serious lacerations occur during parturition. They may occur during normal parturition or can be iatrogenic during intervention to correct a dystocia by mutation or fetotomy. Although one should examine the cervix digitally after a difficult foaling or dystocia, especially if a fetotomy procedure is involved, one can evaluate the extent and severity of a cervical laceration best once the cervical lesion is healed. One should evaluate the competency of the cervix during diestrusor when the mare is under the influence of exogenous progestogens, thus verifying its ability to close tightly. One can more easily diagnose transluminal adhesions and anatomic defects by digital examination of the cervix rather than by vaginoscopy. Because surgical correction is difficult and not always rewarding, one should takea biopsy sample of the uterus to assess the potential of the mare to maintain a pregnancy before one attempts surgical correction of a cervical laceration.

16.3.3.3 POLYPS OR CYSTS

Occasionally, pedunculated cystlike structures are apparent on visual or manual examination of the cervix. These structures are attached to the cervical os or emanate from the cervical lumen and protrude into the vaginaor uterine body. Although of unknown cause, they do appear to be associated with infertility, and removal by laser or ligation is recommended.

16.3.4 Uterus

16.3.4.1 VENTRAL SACCULATIONS

Aside from changes associated with pregnancy, other pathologic conditions cause focal enlargements in the ventral portion of the uterus. These uterine changes usually are associated with increased age and parity and invariably are found at the base of either or both uterine horns, where pregnancies usually are established. Inexperienced palpators may mistake these enlargements for a pregnancy, especially if they do not use ultrasonography to back up their palpation findings. Mechanisms contributing to formation of ventral uterine enlargements have been identified, including but not limited to endometrial atrophy, focal myometrial atonia, and lymphatic lacunae.[8] Furthermore, in older and multiparous mares the uterus may tilt ventrally in relation to the pelvic brim (uterine splanchnoptosis). Mares with ventral sacculations and uterine splanchnoptosis have a higher incidence of delayed uterine clearance than normal mares.[9]

16.3.4.2

ENDOMETROSIS

Endometrosis has been referred in the past as chronic infiltrative endometritis and currently refers to the presence of fibrosis in the stromal and periglandular compartments. The degree of endometrosis is associated closely with the ability of a mare to establish and maintain a healthful pregnancy until term. Parity and age contribute to degenerative changes occurring in the endometria of mares.[10]

Fibrotic changes may occur around the endometrial glands and in association with the basement membrane in the stratum compactum. The amount and pattern of distribution of the fibrotic tissue has been classified descriptively as slight, 1 to 3 layers of periglandular fibrosis; moderate, 4 to 10 layers; and severe, more than 10 layers of periglandular fibrosis.[11] Cystic glandular dilation is another manifestation of endometrosis. Periglandular fibrosis, glandular epithelial hypertrophy, or inadequate lymphatic drainage may lead to dilationof the endometrial glands.

Other degenerative alterations in the endometrium that lead to endometrosis include lymphatic lacunaeand 1042
angiosis.[10,12] Lymphatic lacunae are histopathologic indications of lymphangiectasia. Angiosis (a vascular 1043
pathologic condition) is associated with aging and parity, especially in uteri with ventral sacculations and associated venous congestion, which are pathogenic factors for angiosis.[12] No treatments exist for these anatomic and vascular degenerative changes in the uterus. Mares with lymphatic lacunae and disseminated uterine angiosis are at risk for infertility caused by delayed uterine clearance and persistent mating-induced endometritis.[10,12]

Pregnancy loss attributed to endometrial fibrosis more commonly manifests during the embryonic period. Abortion during the early fetal period may occur, however, if uterine fibrosis interferes with implantation of the placenta. Microcotyledonary attachments begin to develop by 80 to 120 days of gestation.[13] Ultrastructural evaluation of the placenta in mares with chronic degenerative endometritis (endometrosis) has shown a delay in microcotyledon development and a reduction in the number of microcotyledons and villi per surface area. Endometrial atrophy may not result in abortion butcan influence fetal growth. Fetal weights in mares with degenerative endometritis were lower than in normal mares.[14] Evidence of endometrial atrophy may be evident on inspection of the placenta after delivery.[15]

16.3.4.3

ENDOMETRITIS

Whereas endometrosis reflects chronic structural changes associated with age and parity, endometritis encompasses endometrial changes associated with acute or chronic inflammation. These changes are modulated by the action of a local immune system and influenced by the hormonal milieu. A transient endometritis normally occurs in all mares that were mated naturally or artificially inseminated. Mares mount an inflammatory reaction in response to the presence of semen in the uterus, but this apparently normal inflammatory response subsides (histologically) within 2 to 3 days. Detection of intrauterine fluid by ultrasonography per rectum 24 hours after mating suggests delayed clearance. Persistent mating-induced endometritis is a clinical entity that has been recognized as a major cause of infertility in mares.

16.3.4.4 ENDOMETRIAL BIOPSY

An endometrial biopsy often is considered a routine part of a complete breeding soundness examination. Because an endometrial biopsy can aid in predicting the chances of a mare carrying a foal to term, one should consider the information provided by a biopsy before purchase or undertaking reproductive surgery such as repair of a cervical tear. Biopsies in some cases provide information that is useful in the diagnosis of infertility and may provide a basis for treatment. One must realize, however, that an endometrial biopsy alone is not the only, nor usually the most important, piece of information and must be taken in context with other information obtained from the history and reproductive examination.

Generally, one takes a biopsy specimen from a siteat the base of one of the uterine horns. When procuringa biopsy, one should take care not to obtain tissue from a site near the internal cervical os. Glands are less dense near the cervix, making a biopsy obtained from that area less representative of the uterus and more difficult to interpret. Moreover, accidentally taking a biopsy sample from the cervix can result in adhesions.

A single biopsy long has been considered to be representative of the entire uterus; however, studies have shown that variation by as much as an entire category may exist between sites.[16] Therefore one first should perform a thorough examination by palpation and ultrasonography to determine whether any areas of the uterus appear to be abnormal. If one detects an abnormal area, one should obtain biopsy samples from the abnormal and the normal areas. Repeated or multiple biopsies do not significantly affect fertility. A mare may become pregnant when bred just a few days after taking of a biopsy specimen.[17]

One may take biopsy samples at any time during the year or during any stage of the estrous cycle, becausethe cervix is dilated easily. Some clinicians prefer to obtain a biopsy sample during diestrus when the endometrial glands are under the influence of progesterone, whereas others recommend taking the sample during estrus because of the ease in passing the instrument through the cervix. One must relay all pertinent history, including the estrous stage during which the biopsy sample was obtained, to the pathologist reading the sample. Periglandular fibrosis may appear worse in biopsy samples taken during anestrus because of the sparseness of glands. In addition, biopsy samples taken during anestrus or transition may have evidence of increased inflammation because the cervix has been in a relaxed state for a prolonged period because of the absence of progesterone.

Endometrial biopsies are classified into four categories (I, IIA, IIB, III).[18] A mare with a category I biopsy has an essentially normal endometrium. The likelihood of the mare becoming pregnant and carrying a foal to term, estimated at 80% to 90%, depends more on broodmare management than on the inherent fertility of the mare. Mares with a category III biopsy have severe pathologic changes in the endometrium and an estimated 10% chance of carrying a foal to term even with good breeding management. Most mares are classified as a category IIA or IIB with an estimated 50% to 80% and 10% to 50% chance, respectively, of carrying a foal to term, reflecting a combination of management practices and the inherent fertility of the mare.

The pathologist usually provides a complete histopathologic description, but for the practitioner to review the biopsy slide is beneficial because this can be helpful in developing a therapeutic plan for the mare. The primary concern to a clinician is the severity and distribution of inflammation and the presence of 1043
degenerative changes such as periglandular fibrosis, angiosis, and lymphatic lacunae (enlarged and dilated lymphatics). Degenerative changes carry a worse prognosis than inflammatory changes because they are considered to be permanent and progressive. No effective treatment for these conditions has been identified. The cause of such degenerative conditions is not known but is presumed by many to be caused by repeated 1044

insults to the uterus. These conditions more commonly occur in older mares.[10] Dilated lymphatics often indicate a uterine clearance problem. However, one can diagnose delayed clearance more reliably by ultrasonographic examination in the postmating period.

Although biopsy can reveal the presence of an inflammatory condition, one must use other methods (suchas examination of perineal conformation) to reveal why the condition is present, and a culture is needed to identify the particular pathogen. A repeat biopsy after appropriate therapy may reveal the degree of success of treatment and aid in determining a prognosis for future fertility.[19]

16.3.4.5 ENDOMETRIAL CYSTS

Endometrial cysts often are cited as a cause of infertility; however, a cause-and-effect relationship has not been established clearly. The proportion of mares with endometrial cysts increases with age. Mares more than 11 years of age are more than 4 times as likely to have endometrial cysts as are younger mares, and most mares more than 17 years of age have endometrial cysts. Reports that associate endometrial cysts with a lower pregnancy rate or increased embryonic loss fail to account for the effect of advancing age. When one controls for confounding effects such as parity and age, the assumption of cysts causing infertilityis not supportable. When confounding factors were accounted for in the analysis of nearly 300 mares, endometrial cysts did not have a statistically significant effect on establishing or maintaining pregnancy, although the time of initial pregnancy diagnosis was not controlled strictly.[20] Another report by a different group of researchers who did control the time of pregnancy diagnosis similarly found no difference in pregnancy loss between mares with cysts versus those without, although mares with endometrial cysts tended to have a lower day 40 pregnancy rate. The effect of cysts on fertility appeared to be quantitative because an effect was not evident until a mare had numerous cysts or the cysts were large. However, even then the effect of endometrial cysts on fertility was much less than that with delayed uterine clearance or intrauterine fluid accumulation. A quantitative effect of endometrial cysts could be caused by interference with embryonic mobility. A well-known fact is that the equine embryo undergoes a period of mobility after entering the uterus, finally becoming fixed in place at approximately 16 or 17 days of gestation. If mobility is restricted during this period and the embryo is not permitted to contact a sufficient portion of the endometrium, maternal recognition of pregnancy may not occur, resulting in luteolysis and embryonic loss.

Rather than viewing endometrial cysts as a cause of infertility, one should consider them as an indication of underlying pathologic changes in the uterus. Endometrial cysts are of lymphatic origin, and their occurrence may be associated with a disruption of lymphatic function.

Endometrial cysts are diagnosed best with ultrasonography. One can identify cysts as hypoechoic, immovable structures with a clear border, as opposed to intraluminal fluid, which is movable and has a less distinct shape or border. Endometrial cysts are usually multiple and most commonly are found at the base of the uterine horns. Cysts may change in size and number between estrus and pregnancy.

Endometrial cysts can complicate early pregnancy diagnosis. Often an endometrial cyst can be similar in size and appearance to an early conceptus. Cysts that appear spherical often can be shown to have a more irregular shape if the ultrasound probe can be reoriented in relation to the cyst. To make early pregnancy diagnosis easier and more reliable, one should record the size and location of endometrial cysts using a diagram or by storing ultrasonographic images during a prebreeding examination. Even so, one may need to repeat the pregnancy examination or delay confirmation in some mares with endometrial cysts. In most cases of endometrial cysts, no treatment is necessary other than recording their size and location for future reference during pregnancy examination. However, if the cysts are sufficientin size or number that they pose

a potential threat to embryonic migration, treatment can be aimed at facilitating establishment of pregnancy by providing exogenous progestogen.

Progestogen, usually in the form of altrenogest (0.044 mg/kg p.o. daily), can maintain pregnancy even when the signal for maternal recognition of pregnancyis lacking. Numerous studies have shown the ability of altrenogest to maintain pregnancy after luteolysis orin ovariectomized mares. One must emphasize that if progestogen therapy is deemed necessary, the correct dose and frequency of administration is required or the effort is wasted. For example, once weekly injections of progesterone in oil or once a month administration of medroxyprogesterone are insufficient to maintain pregnancy and therefore would not be beneficial in mares with large or numerous endometrial cysts.

Alternatively, one may remove endometrial cysts surgically. Laser surgery is an ideal method if the equipment is available. Ligation and transection of the stalk of pedunculated cysts is an alternative. Merely 1044
puncturing and draining the cyst or incising its wall does not provide long-term remission. 1045

16.3.4.6 TRANSLUMINAL ADHESIONS

Severe infectious or chemically induced (following intrauterine infusion of irritating chemicals) endometritis may induce the formation of transluminal adhesions in the uterus. These lesions are asymptomatic and found during hysteroscopy. Uterine adhesions may cause the retention of endometrial secretions, resulting in mucometra or pyometra. Early embryonic motility, a phenomenon paramount for maternal recognition in horses, may be impaired by intraluminal adhesions. Treatment modalities include manual disruption of intraluminal adhesions or ablationvia laser surgery.

16.3.4.7 PYOMETRA

Pyometra is an accumulation of purulent exudate in the uterus. Unlike cows, mares with pyometra do not necessarily have a persistent corpus luteum and many may cycle normally. A cervical anatomic defect that prevents the clearance of fluid from the uterus may predispose mares to pyometra. However, this condition also can affect mares without an apparent anatomic defect in the reproductive tract. One can diagnose pyometra readily by transrectal ultrasonography when intraluminal fluid with moderate echogenicity is visible in the uterus. Because most mares with pyometra are brought to the veterinarian's attention at an advanced stage, degenerative changes such as endometrial atrophy may preclude mares from returning to normal fertility after treatment. One should examine a biopsy sample of the uterus before treatment to determine the prognosis for potential fertility. Although one can attempt medical evacuation of the uterus, hysterectomy is an option for mares refractory to treatment or with advanced degeneration of the endometrium (severe endometrosis).

16.3.4.8 NEOPLASIA

Uterine neoplasms are uncommon in mares. Leiomyomas, often referred to as fibroids, are benign mesenchymal neoplasms derived from smooth muscle and often are associated with the presence of fibrous tissue. Leiomyoma is the most common neoplasm affectingthe uteri of mares and if small does not necessarily cause reproductive failure. Leiomyosarcoma, lymphosarcoma, and adenocarcinoma are rare malignant neoplasms affecting mares.

One usually discovers neoplasms affecting the equine uterus when palpating per rectum and performing transrectal ultrasonography in broodmares during the breeding season. If one suspects the presence of a

uterine neoplasm, one should perform uterine endoscopy and take a biopsy sample of the tissue for final diagnosis. Surgical excision of neoplasms is indicated when extensive hemorrhage and endometritis are present or when the presence of the neoplasia would be incompatible with establishing a pregnancy. Prognosis for future fertility is reduced, but pregnancy has been reported in mares with partial hysterectomy.[21]

16.3.4.9 UTERINE LACERATIONS

Uterine lacerations can occur during unattended or assisted parturition. Palpation per rectum and per vaginum and abdomino-centesis aid diagnosis.[22] Adhesions involving the serosal surface of the uterusmay occur following cesarean section or uterine tears. No effective treatment, other than attempted surgical excision, exists once the adhesions form. Therefore one should take steps to minimize the likelihood of adhesion formation, including daily palpation of the uterus after cesarean section.

16.3.4.10 UTERINE ARTERY RUPTURE

Age and parity are contributing factors for mares atrisk for uterine artery rupture.[23] Uterine vessels undergo extensive dynamic remodeling during pregnancy and the postpartum period, and this is thought to contribute to progressive degenerative vascular changes. Intravenous administration of formalin or naloxone (a μ-opioid receptor antagonist) have been reported anecdotally to control hemorrhage after uterine artery rupture in postpartum mares. Recently, administration of safe doses of formalin to healthy horses has been shown not to alter any of the hemostatic variables analyzed.[24] If a mare survives an acute episode of rupture of the uterine artery, antimicrobial therapy is indicated to prevent the hematoma from becoming an abscess. Monitoring the mucous membranes and pulse for 30 minutes after foaling is indicated in the event the parturition was induced or assisted by a veterinarian, and especially when an intervention to correct a dystocia is performed.[25] In mares that survive a ruptured uterine artery, fertility is not altered, but mares may suffer fatal hemorrhage during the subsequent parturition.

16.3.5 Uterine Tubes

The function of uterine tubes is essential for normal fertility. The passage of equine embryos throughout the uterine tube is longer than for other domestic species, which underlines the importance of the tubal environment for normal fertility. Mares are also unique in that unfertilized oocytes are retained in the uterine tubes and are not transported to the uterus. The mechanism(s) accounting for this phenomenon (selective transport of fertilized versus unfertilized oocytes) has not yet been elucidated fully but appears to involve secretion of 1045

1046 prostaglandin E_2. A healthy uterine tube responds to embryonic signals, resulting in proper timing of tubal transport. Diagnosis of pathologic conditions in the uterine tubes is difficult and often occurs only in postmortem examinations.

Postmortem examination of reproductive tractsfound that salpingitis was common in mares; 37% had infundibulitis, 21% had ampullitis, and 9% had isthmitis. In that study, 50% of mares were more than 15 years old and 85% were more than 11 years old. The infundibulum generally was found adhered to the uterus, mesovarium, or ovary. The incidence of adhesions on the right side was significantly higher than on the left side.[26]

Postmortem analysis of uterine tubes has suggested that tubal patency is not a major problem in mares. Oviductal obstructions are less common in the mare than in the cow, although masses of collagen have been found in the oviducts of young maiden mares and pregnant mares and were observed more often in mares more than 7 years old.[27] An examination of 700 postmortem specimens, primarily from mares more than 11 years old, found that almost all oviducts were patent, although more than 40% had adhesions involving the infundibula.[26] Only one uterine tube was found to be occluded among 1248 pairs of uterine tubes that were flushed post mortem.[26,28] Based on these findings, diagnostic procedures to determine the patency of uterine tube in mares with unexplained infertility are not warranted.

16.3.6 Ovary

The presence of an enlarged ovary in a mare may be normal or may be an indication of a pathologic ovarian condition. Consideration of the various possibilities and careful diagnostic procedures are necessary to avoid surgical removal of normal ovaries. A thorough history, including changes in behavior, estrous cycle characteristics, sexual behavior, and the last observed estrus is important to consider. Ultrasonography, palpation, and hormonal assays are helpful in arriving at an accurate diagnosis. In some mares, sequential examinations are beneficial in determining changes in the size of ovaries or various structures on an ovary.

Discovery of an enlarged ovary may be an incidental finding during a normal reproductive examination or may be stimulated by specific clinical signs. Behavioral changes or signs of colic in a mare warrant examination of the reproductive tract, with special attention to the ovaries. Mares with a history of infertility often are suspected of having abnormalities of the ovaries and deserve a thorough examination before surgical removal of an enlarged ovary. One must take into consideration various factors such as season and pregnancy status when interpretinga finding of ovarian enlargement. Large ovaries may be normal during the transitional periods in the spring and fall and are expected during certain stages of gestation.

16.3.6.1 NEOPLASIA

Granulosa-theca cell tumors are the most common tumors of the reproductive tract in mares. They are benign sex-cord tumors that can occur in any age mare and have been reported in foals, aged mares, and pregnant mares. Although the granulosa and the theca interna cell layers may be involved, the granulosa cell layer most commonly is affected.

Behavioral changes are common in mares with granulosa cell tumors. Behavior may be stallionlike, persistent estrus, or persistent anestrus, depending on the steroid production of the tumor. In other cases of granulosa cell tumors, behavior may be unchanged yet the mare may be showing signs of abdominal discomfort, lameness, or anemia or other signs seemingly unrelated to the reproductive system. Stallionlike behavior is the most commonly reported behavioral change observed, possibly because the change from previous behavior is obvious to the owner and causes an increased challenge in handling the mare. In one report of 63 mares diagnosed with granulosa cell tumors, 20 exhibited anestrus, 14 were in persistent estrus, and 29 showed stallionlike behavior. Stallionlike behavior usually is associated with elevated serum testosterone. However, persistent estrus has not been correlated with elevated estrogen.

On palpation per rectum, the affected ovary is enlarged, whereas the contralateral ovary is typically small and inactive. Atrophy of the contralateral ovary canbe misleading during winter anestrus when ovaries are typically small and inactive. Atrophy of the contralateral ovary is not absolute. Although unusual, granulosa

cell tumors have been reported in pregnant mares and in cyclic mares with a functional contralateral ovary and even in both ovaries.[29] The enlarged ovary may be smooth or knobby, hard or soft, and may feel like multiple follicles are present. Typically, one cannot palpate the ovulation fossa on the enlarged ovary, although with any greatly enlarged ovary, the fossa may be difficult or impossible to palpate.

Ultrasonographic evaluation often shows the classic multiloculated appearance. However, sometimes the tumor may appear solid or with larger cystlike hypoechoic areas.[30] Although ultrasonography is a useful adjunct, it may not yield a definitive diagnosis in many cases. The ultrasonographic image of granulosa cell tumors can be similar to that of other ovarian abnormalities, especially ovarian hematomas. A variety of reported appearances make diagnosis based solely on ultrasonography impossible in many instances.

Mares with granulosa cell tumors may have elevated concentrations of estrogen or testosterone, but 1046
progesterone is almost always less than 1 ng/ml. Measurement of estradiol is of limited value. Although 1047
testosterone often is elevated in mares with granulosa cell tumors exhibiting stallionlike behavior, testosterone is within normal limits in 10% to 50% of cases. Testosterone in normal cycling mares is approximately 45 pg/ml and often is greater than 100 pg/ml in mares with stallionlike behavior. McCue reported that only 54% of mares with granulosa cell tumors had elevated testosterone, yet 87% had elevated inhibin, leading to the conclusion that inhibin is a better indicator of the disease.[31] Inhibin suppresses follicle-stimulating hormone, which leads to a decline in follicular growth, thus explaining the profound negative feedback effect on the contralateral ovary.

Overall, the prognosis for life and reproductive function in a mare with a granulosa cell tumor is good. Depending on the time of year when the ovary is removed, the individual mare, and the length of time the tumor has been present, resumption of ovarian activity usually occurs83 to 392 days after surgery, with a mean of 209 days. If the intended use of the mare is solely as a broodmare, a reproductive examination, including a uterine biopsy, is recommended before surgery.

Teratomas, although uncommon, are the second most common ovarian tumors. They contain at least two ifnot all three germinal layers. Most teratomas found in mares are benign. They usually contain hair and alsomay contain bone, teeth, and neural tissue. Teratomas are usually an incidental finding because most are small and do not often cause significant ovarian enlargement. However, on occasion, large teratomas develop that result in ovarian enlargement. Teratomas do not affect the estrous cycle and therefore lack obvious outward clinical signs.

Serous cystadenomas are neoplasms of epithelial origin usually found in older mares. These tumors do not metastasize. Although they have been found in mares with high plasma testosterone,[32] behavioral changes are not characteristic. The contralateral ovary is not affected, continues to have normal activity, and does not atrophy; and affected mares continue to cycle. On the affected ovary, the ovulation fossa is not obliterated and is palpable.

Dysgerminomas are highly malignant tumorsalso of germ cell origin. They metastasize rapidly tothe abdominal and thoracic cavities and are considered the counterpart of the testicular seminoma. Because of their nature, dysgerminomas can affect other organ systems, and cases have been reported of associated hypertrophic pulmonary osteoarthropathy.[33] Clinical signs on presentation therefore often are unrelated tothe reproductive system. These tumors carry a poor prognosis.

16.3.6.2

OVARIAN ABSCESS

Ovarian abscesses often are attributed to procedures involving puncture of the ovary, such as biopsy or follicle aspiration. As assisted reproductive techniques became more successful and therefore more popular, the incidence of ovarian abscesses was thought likely to increase. However, this has not proved to be the case. Moreover, not all ovarian abscesses can be attributed to iatrogenic causes. Ovarian abscesses have been reported in mares that have had no such procedures performed on them. In these cases, they are likely caused by the hematogenous spread of bacteria or may be associated with strongyle migration.

Affected mares may be febrile and anorectic with an elevated white blood cell count. On ultrasonographic examination, the enlarged ovary typically has a thick-walled, fluid-filled structure. The fluid is usually hyperechoic. Medical management with long-term antibiotic therapy has been successful in treating these cases. Surgical removal of the affected ovary is an alternative treatment, but one must take care that the abscess does not rupture in the abdominal cavity.

16.3.6.3

OVARIAN TORSION

Ovarian torsion, a condition not uncommon in women, has been reported in a mare with a large granulosa-theca cell neoplasm and showing signs of abdominal discomfort.[34] One may suspect ovarian torsion in mares with known ovarian enlargement, if sudden signs of abdominal pain develop.

16.3.6.4

NONNEOPLASTIC OVARIAN ENLARGEMENT

An ovarian hematoma forms as hemorrhage occurs into the previous follicular lumen after ovulation. On occasion, this hemorrhage can be excessive, possibly because ofan anticoagulant in follicular fluid. Hematomas can be large, up to 20 cm in diameter or more. They are able to produce progesterone and do not affect the estrous cycle. Although the ovulation fossa is still present, palpating it can be difficult if the hematoma is large. The ultrasonographic appearance can vary, causing confusion with a granulosa cell tumor. One may observe large, fluid-filled cavities, or the hematoma may have a more solid appearance, sometimes with fibrin strands. A trait that is at times useful in differentiating a hematoma from a granulosa cell tumor is the responsiveness to prostaglandin. Hematomas that are at least 5 or 6 days old often respond to prostaglandin by decreasing in size because of the luteolytic effect. Granulosa cell tumors do not respond to prostaglandin treatment with any change in size, shape, or ultrasonographic appearance. Because the follicle wall still undergoes luteinization despite the presence of the hematoma, cyclicity remains unaltered, 1047
thus normal fertility is not compromised. However, the enlargement of the ovary because of the presence of a 1048
hematoma may persist for several estrous cycles even though the life span of the luteal tissue is normal. Because this structure isa postovulatory phenomenon, the oocyte has been released and the mare may become pregnant if she was mated.

Anovulatory follicles most commonly occur in mares near the end of the breeding season as they go through the autumn transition. These follicles grow to an unusually large size (70 to 100 mm) yet fail to ovulate. Instead, they fill with blood and develop a gelatinous consistency. A thick (compared with a normal follicle) wall commonly forms. The follicles become firmer and then regress over time, usually disappearing within a month. With ultrasonography one observes free-floating echogenic spots in the antrum of the follicle that increase in number as the follicle grows. When the follicle stops growing, the contents become organized with an echogenic appearance and fibrin strands. Formation of luteal tissue around the periphery of the

anovulatory follicle is usually minimal in a true autumnal follicle that occurs at the end of the season. The cause of anovulatory follicles is unknown, although they are hypothesized to be caused by changes in the hormonal status of the mare that occur with autumn transition. This hypothesis does not explain the occasional occurrence of anovulatory follicles during the breeding season, however. Luteinized anovulatory follicles, although unusual during the ovulatory season, most often occur in older mares and may be associated with senility. Their response to prostaglandin varies.

During certain periods of gestation, ovarian enlargement is normal and should be expected. Ovarian enlargement is associated with increased follicular activity and subsequent ovulation (secondary corpora lutea) or anovulatory luteinization (accessory corpora lutea). An increase in follicular growth begins before day 20of gestation. New corpora lutea form around day 40 of gestation. Corpora hemorrhagica and hemorrhagic follicles commonly occur from day 40 to 60. Maresbred early in the season have greater follicular activity during the first 4 months of gestation than mares bred after July.

During the spring as mares undergo transition from winter anestrus to the normal ovulatory season, they undergo periods of prolonged anovulatory follicular development. These periods are characterized by the development of numerous follicles, at times large, on either ovary or usually both ovaries. The follicles may persistfor varying lengths of time and then regress, and new follicles develop. This period lasts for a variable time depending on the mare, photoperiod, and other undetermined factors. The ovaries can be large during this time and mistakenly may be called cystic. No treatment is necessary, although a combination of progesterone and estrogen often is used to suppress follicular activity in an attempt to hasten the onset of ovulation and normal cyclicity. The transition period ends with the first ovulation of the season, after which follicular activity and ovarian size return to normal.

Small and inactive ovaries normally are found in mares in deep anestrus, prepubertal mares, and pregnant mares in the last third of gestation when, curiously, the fetal gonads are larger than the ovaries of the dam. Mares subject to severe malnutrition, mares of advanced age, mares treated with anabolic steroids, and mares with chromosomal alterations leading to gonadal dysgenesis may have abnormally small and inactive ovaries.

16.4

16.4—Endometritis and Uterine Therapy

Nigel R. Perkins

Endometritis is a major problem facing veterinarians treating studs and attempting to maximize per cycle conception and foaling rates. Recent advances have improved understanding of the pathogenesis of endometritis and have resulted in more effective methods to minimize the affect on fertility. Endometritis has been categorized into persistent mating-induced endometritis, chronic infectious endometritis, chronic degenerative endometritis, and sexually transmitted diseases.[1–3]

Failure of mechanical clearance of fluid, debris, and inflammatory by-products from the uterine lumen is recognized as the major predisposing factor associated with development of infectious endometritis.[4–6] Diagnosis of infectious endometritis is based on one or more of the following: ultrasound detection of echogenic uterine luminal fluid and acute inflammatory change on endometrial cytologic examination or biopsy along with a positive endometrial culture. One may suspect the condition in mares with cervical, vaginal, or vulval discharge during estrus.

Diagnosis of chronic degenerative endometritis is based mainly on observation of fibrotic changes in endometrial biopsy samples and is most commonly a condition of older mares. Mares may have a history of failing to conceive over successive cycles or seasons, recurrent or chronic endometritis, and pregnancy loss before 60 days.

Sexually transmitted diseases include contagious equine metritis *(Taylorella equigenitalis)*, *Pseudomonas aeruginosa*, and *Klebsiella pneumoniae*. Susceptible mares bred to a contagious, bacteria-shedding stallion with contagious equine metritis usually show shortened interovulatory intervals with a copious mucopurulent genital tract discharge associated with vaginitis, cervicitis, and endometritis. Diagnosis depends on recovery of the causative organism from culture samples taken fromthe uterus, cervix, clitoral fossa, and clitoral sinuses. The organism is difficult to culture and requires careful sampling, specific transport media, chilling during shipment, and appropriate incubation environment in a laboratory skilled at microbiologic procedures. The veterinarian should speak to the regional laboratory before culturing a mare for suspected contagious equine metritis. *P. aeruginosa* and *K. pneumoniae* are present in most equine breeding populations as occasional genital tract

pathogens withthe possibility of sexual transmission. Diagnosis and treatment in the mare is as for other causes of infectious endometritis, though owners should withhold mares from natural breeding until the infection is eliminated. 1049

1050

One should base the choice of uterine therapies for endometritis on the same fundamental principles as for pharmacotherapy in other body systems. The anticipated therapeutic benefit should outweigh the potential risks associated with the disease and the treatment. Historical use of a particular treatment does not justify continued use unless clear evidence documenting efficacy and safety accompanies the treatment. Many of the therapies described in this section are based on empirical evidence alone.

Drug preparations must be nonirritating if they areto be used in the genital tract of the mare. Almost any substance, including physiologic saline, induces an inflammatory response when introduced into the uterus of the mare.[7] Understanding this is particularly important when one treats the mare around the time of breeding, because an inflammatory response that is severeand that persists for longer than 5 days after ovulationis likely to interfere with embryo survival once the embryo enters the uterine lumen at about day 6 after ovulation.

16.4.1 Antimicrobial Therapy

The use of antimicrobial agents to treat and prevent endometritis is based largely on empirical evidence. Pharmacokinetic studies on which to base recommendations regarding choice of drug, route, dose, and frequency of administration are few. Table 16.4-1 shows recommended doses for various preparations commonly infused into the uterus of the mare.

16.4.2 Intrauterine Versus SystemicAntibiotic Therapy

Antibiotics, which have been recommended as possible systemic treatments for equine endometritis, include amikacin sulfate, ampicillin trihydrate, gentamicin sulfate, procaine penicillin, and trimethoprim-sulfadiazine. Dose rates, routes, and frequency of administration usually follow published guidelines for administration of these drugs for other conditions (see Chapter 4 for a detailed discussion).[8]

Several hypothesized advantages have been associated with systemic antibiotic therapy as opposed to intrauterine infusion. Parenteral administration eliminates the risk of bacterial contamination of the reproductive tract associated with repeated intrauterine infusions. Uterine tissue concentrations of ampicillin and enrofloxacin are higher than serum concentrations after intravenous or oral administration of the drugs.[9,10] Some drugs may be associated with an adverse local tissue reaction when administered into the uterine lumen and yet not have any adverse effect on uterine tissue when administered systemically. For example, intrauterine infusion of enrofloxacin has been linked to uterine pathologic conditions including adhesion formation. Enrofloxacin has been associated with cartilage and skeletal damage in young, growing horses and with joint effusion and mild cartilage lesions in adult horses following systemic use.[10] Nontheless, mares receiving enrofloxacin orally (5 mg/kg every12 hours p.o. for 21 days) had endometrial tissue concentrations higher than those observed in serum, and all tissue levels of drug exceeded minimum inhibitory concentrations (MICs) for common equine pathogens. Further work is required before this product can be recommended as a treatment for endometritis.

Little documentation exists of efficacy of systemic therapy in treating endometritis. Authors have suggested that systemic therapy be considered in cases in which deeper layers of the uterus are infected or inflamed, asin

the case of postpartum metritis.[3,7] The author routinely uses systemic antibiotic therapy only in cases in which the mare shows systemic signs of illness associated with the reproductive tract.

Most uterine infections in the mare are limited to the lumen and the superficial endometrium. Local uterine therapy via uterine infusion is favored for treating such conditions because it is considered likely to result in high antibiotic concentrations within the lumen and superficial layers of the endometrium. In addition, uterine infusion of antibiotic is often more economical than systemic therapy.

16.4.2.1 CHOICE OF ANTIBIOTIC

Factors to consider in choosing an antibiotic to use in the uterus include types of organisms isolated, antibiotic sensitivity patterns of isolated organisms, and potential efficacy of the drug in the uterus. Antibiotic selection should be as specific as possible and should be based on microbiologic isolation of the causative organism(s) by uterine culture, followed by sensitivity testing.[11] The use of broad-spectrum antibiotics in the absence of culture and sensitivity results is discouraged because indiscriminate use of antibiotics is considered likely to increase the risk of adverse sequelae such as resistance and superinfection with different bacterial strains or with fungi or yeast.[7] Use of antibiotic combinations also may be inappropriate because of the risk that incompatibilities will reduce efficacy. An example is the suggested inactivation thought to occur when β-lactam antibiotics such as penicillin are combined with aminoglycosides such as gentamicin.[12]

However, a strong argument also exists that the first choice of antibiotic for intrauterine use should be a broad-spectrum combination of drugs aimed at successfully treating all components of the mixed aerobic and anaerobic infections that commonly occur.[13]

In cases in which culture and sensitivity results arenot available, one should base the choice of drug on the 1050
expected bacterial organisms involved and the predicted antibiotic susceptibility patterns.[12] 1051

TABLE 16.4-1 Recommended Doses of Intrauterine Drugs

DRUG	DOSE	COMMENT
Amikacin sulfate	1–2 g	Gram-negative microorganisms
Ampicillin	1–3 g	
Carbenicillin	2–6 g	*Pseudomonas*
Ceftiofur	1 g	Broad spectrum
Gentamicin sulfate	0.5–2 g	Excellent gram-negative
Kanamycin sulfate	1–2 g	*Escherichia coli;* toxic to sperm
Neomycin	3–4 g	
Nitrofurazones	50–60 ml	Questionable efficacy
Penicillin (Na or K salt)	5,000,000 IU	Streptococci
Penicillin G procaine	3,000,000–6,000,000 IU	Streptococci
Polymixin B	40,000–1,000,000 IU	
Ticarcillin	1–6 g	Streptococci, *E.coli, Pseudomonas;* poor against *Klebsiella*
Trimethoprim-sulfadiazine	120 mg	
COMBINATIONS		
Neomycin	1 g	
Polymixin B	40,000 IU	
Furaltadone	600 mg	
Penicillin (Na or K salt)	3,000,000–5,000,000 IU	
Neomycin	2 g	
Penicillin G procaine	3,000,000 IU	
Gentamicin sulfate	0.5–2 g	
Penicillin G procaine	3,000,000–6,000,000 IU	
ANTIFUNGAL THERAPIES		
Nystatin	250,000–1,000,000 IU	Mix with sterile water. Precipitates in saline.
Amphotericin B	200–250 mg	
Clotrimazole	300–600 mg	Every 2 to 3 days for 12 days
Clotrimazole cream	500 mg	Daily infusion for 1 week
Vinegar	2% solution	20 ml wine vinegar in 1 L saline
Povidone-iodine	1%-2% solution	
IRRITANTS		

Chlorhexidine	1%-2% of stock solution	
Dimethyl sulfoxide	5% solution	Infuse 50 to 100 ml.
EDTA-tris	1.2 g EDTA plus 6.05 g tris per 1 L water	Titrate to pH 8.0 with glacial acetic acidic. Infuse, wait 3 hours, and then infuse antibiotic.
Hydrogen peroxide	1:4 dilution with saline	
Kerosene	50 ml	Avoid reflux through cervix.
Povidone-iodine	0.05% solution	
Saline	Variable volume	Consider warming to 45 to 50 C.
Streptococcal cell–free filtrate		
Modified from Perkins NR: Equine reproductive pharmacology, *Vet Clin North Am Equine Pract* 15(3):687–704, 1999.		

One may isolate virtually any bacterial species from acute endometritis. Several studies have reported that 70% to 80% of acute, aerobic endometritis cases were associated with *Streptococcus zoopepidemicus*, *Escherichia coli*, *P. aeruginosa*, and *K. pneumoniae*.[12,14,15] Large-scale data from routine endometrial cultures in the United Kingdom appear to show a slightly different pattern of bacterial involvement. Of 3414 isolates associated with cytologic evidence of endometritis, 38% were recovered in pure culture and 62% in mixed culture.[16] The role of anaerobic bacteria in endometritis remains unclear. One study has reported that in 18 of 71 (25%) mares in which endometrial cytologic tests and cultures were positive, an anaerobe was the sole isolate cultured. The most common anaerobe recovered was *Bacteroides fragilis*.[17] Others have suggested that anaerobes are unlikely to play a significant role in endometritis.[18]

No single antimicrobial therapy is effective against all of the commonly isolated uterine pathogens. β-Lactam antibiotics (penicillins and cephalosporins) are effective against streptococci. Synthetic penicillins such as 1051
1052 ampicillin and ticarcillin are also effective against many strains of *E. coli* and *P. aeruginosa*. Aminoglycosides are used primarily to treat gram-negative organisms. Bacterial sensitivity patterns often vary, particularly for gram-negative organisms, and accurately predicting sensitivity patterns is not possible in many cases.[12]

The difficulties described in identifying the causative agent in cases of endometritis and in predicting antibiotic sensitivities and the time constraints of a short breeding season mean that in most cases, broad-spectrum antibiotics are used as a first-choice treatment. In many cases, use of a combination of drugs achieves a broad spectrum of activity.

Commonly used broad-spectrum antibiotics include ticarcillin, ampicillin, and drug combinations such as penicillin/aminoglycoside and penicillin/furaltadone/neomycin/polymixin B (Utrin Wash, Univet Ltd, Wedgewood Road, Bicester, UK). Recently, ceftiofur sodium (1 g by intrauterine administration per day for 3 successive days) was used in clinical trials as a broad-spectrum, intrauterine treatment for equine endometritis and was considered to be an effective and safe alternative to the combination of penicillin, neomycin, polymixin B, and furaltadone.[13]

16.4.2.2 ANTIBIOTIC FORMULATION, TREATMENT FREQUENCY, AND VOLUME

Little evidence is available on which to base recommendations regarding dose rate, formulation, volume of drug infused, diluent, and frequency of treatment. Ideally, one should base dose regimens on MIC data along with pharmacokinetic studies of drug disposition following intrauterine administration. In the absence of any information, dose rates apparently are based on the recommended parenteral dose rate for the drug in question. In many cases the dose rate recommended for intrauterine use is lower than the systemic dose. In some cases this is based on clinical evidence, whereas in others it appears to be more a response to convenience or cost. Use of a 2-g dose of amikacin sulfate per intrauterine infusion appears to produce optimal results in mares experimentally inoculated with *K. pneumoniae*.[19,20] Intrauterine treatments are performed commonly every day or every second day for 3 to 7 days. Once daily treatment with 3 g ampicillin has been shown to maintain uterine levels above MIC levels for common equine uterine pathogens for the entire 24-hour period between treatments.[21] Possibly, maintaining uterine antibiotic levels above MIC forthe duration of the time interval between successive treatments is not necessary because exposure of bacteria to large doses of antibiotic for brief periods of time has been reported to increase the susceptibility of bacteria to leucocyte killing.[22] One usually gives treatment during estrus, largely because uterine defense mechanisms are more effective during estrus than diestrus. Treatments may proceed for up to 2 to 4 days after ovulation provided the infused preparation results in little endometrial irritation.

The volume of fluid infused into the uterus of the mare with each treatment ranges from 30 to 250 ml. Several authors have suggested that sufficient volume of fluid should be used to obtain complete uterine coverage when infused.[11,14,23] The capacity of the typical, nonpregnant uterus of a mare is about 35 ml, whereas the uterus of an older mare may hold 60 to 150 ml.[11,14] Another study suggested that infusion of fluid volumes ranging from 30 to 250 ml does not result in uniform distribution of fluid within the uterine lumen. Most of the infused fluid pools in the uterine body and at the body-horn junctions.[24] Most cervical reflux was observed 10 to 15 minutes after infusion, which is consistent with endogenous oxytocin or prostaglandin $F_2\alpha$–stimulated uterine contractions. Larger volumes were more likely to result in reflux through the cervix. Apparently, some of the benefit from infusing antibiotic into the uterus in volumes large enough to encourage cervical reflux actually is from the lavage effect rather than a direct antibacterial effect.

One must take care to avoid insoluble or irritant preparations that might cause chronic endometritis.[25] Drugs for uterine infusion commonly are diluted in saline, balanced electrolyte solutions, or water for injection. Some authors suggest that acid drugs such as gentamicin and amikacin be buffered by mixing equal volumes of antibiotic and 7.5% sodium bicarbonate before infusion into the uterus.[8] Others reported that uterine infusion of gentamicin diluted in saline was no more likely to result in endometrial inflammation than saline alone.[26] Choice of diluent may influence pharmacokinetics of some drugs. Infusion of gentamicin into the uterus of cattle was followed by systemic absorption of more than 60% of the dose when the gentamicin was diluted in water versus less than 20% ofthe dose when diluted with saline.[27]

Veterinarians traditionally have avoided infusing procaine penicillin into the uterus of a mare, perhaps because of an early study based on hysteroscopy that reported that the endometrium was visibly covered with a white, chalky material thought to be antibiotic, following infusion of ampicillin. The material was visible at 3, 7, and 14 days after infusion.[28] Nonetheless, procaine penicillin is used widely as an intrauterine infusion and commonly is mixed with aminoglycosides, particularly gentamicin and neomycin. The use of procaine penicillin in the equine uterus requires additional investigation.

16.4.3 Antifungal Preparations

Dilute povidone iodine or 2% vinegar (20 ml white vinegar in 1000 ml saline) has been proposed as intrauterine 1052
therapy for fungal endometritis. A variety of antifungal medications also have been used as intrauterine 1053
treatments. Too little or no data exist on which to make recommendations regarding sensitivity patterns, doserates, or frequency of treatment. Fungal endometritis hasbeen reported as being difficult to treat, though this perception in part may be caused by use of ineffective or inappropriate treatments.[29]

16.4.4 Antiseptics and Irritants

Antiseptic or irritant therapy commonly has been recommended in cases in which a diagnosis of endometritis has been made but no specific causative agent has been isolated or for aged, subfertile mares with distinct degenerative changes on endometrial biopsy. Irritants have been used to reduce the size of the uterus and increase uterine tone. Antibiotics are not useful in this manner unless they are irritating. In addition, irritants may decrease fluid viscosity within the uterus to aid in its expulsion. Irritant therapy also has been credited with stimulating a severe, acute inflammatory response within the endometrium that may help resolve the chronic, monocytic inflammation commonly associated with degenerative endometritis or endometrosis. Mechanical curettage has been reported to have similar effects, although the technique is difficult because of the bicornuate nature of the equine uterus. The typical endometrial response to infusion of an irritant is a nonspecific inflammatory reaction with hyperemia and neutrophil influx, which then is followed by a slower infiltration of mononuclear cells that peaks 4 to 7 days after treatment. The duration of inflammation and the extent of tissue damage have been reported to vary considerably between individual animals given the same treatment. Irritant therapy also appears to produce a nonspecific activation of endometrial glands.[30] Excessive irritation of the endometrium associated with too harsh or concentrateda solution may result in worsening of the degenerative condition and even in adhesion formation. Chlorhexidine solution has a propensity to cause endometrial adhesions and severe reactions and should not be used within the uterus.[23] Recently, anecdotal evidence suggests that enrofloxacin administered as a uterine infusion in mares may be highly irritating, resulting in a severe inflammatory reaction with serosanguineous uterine fluid containing fibrin tags.

16.4.5 Povidone-Iodine

Dilute povidone-iodine solution is a commonly recommended intrauterine treatment because of its irritant, bactericidal, and fungicidal properties. Bactericidal activity of povidone-iodine is maintained in vitro down to concentrations of 0.01% to 0.005%, whereas more than 0.2% povidone-iodine has been claimed to inhibit neutrophil migration.[31] Stock povidone-iodine solution used in practices to disinfect surgical sites is described as a solution containing 10% povidone-iodine, equivalent to 1% available iodine.

Discussions regarding safety of dilute povidone-iodine solutions in the mare are a good example of the need for critical information on the effects of all potential irritant therapies on the uterus. Earlier studies found severe inflammatory responses in the endometrium following infusions of 2% or more povidone-iodine.[32,33] A similar study reported severe, prolonged irritation of the endometrium following infusion of 1% povidone-iodine solution with mares still showing evidence of inflammation at the conclusion of the study, 30 days following infusion.[34] Others have reported resolution of inflammation on uterine biopsy within 6 days of uterine infusion of 0.05% povidone-iodine solution.[7] In addition, infusion of 1 L of 0.05% povidone-iodine into the uterus 4

hours after breeding was found to have no adverse effect on pregnancy rates.[35] Recently, Bracher reported that infusion of 0.05% povidone-iodine solution into the uterus (alone or combined with dimethyl sulfoxide or collagenase) induced adhesions, ulceration of the endometrium, and severe stromal fibrosis and gland degeneration in three of five treated mares.[30] Individual mares have been postulated to be hypersensitive to povidone-iodine solution. Asbury and Lyle[8] have suggested that any signs of discomfort or irritation on clinical observation or observation via vaginal speculum following povidone-iodine infusion be followed by a saline flush of the genital tract and discontinuation of povidone-iodine therapy. The author suggests that povidone-iodine solutions be avoided or used with caution until further information is available on their safety as a uterine therapy.

16.4.6 Hydrogen Peroxide

Hydrogen peroxide acts as an irritant and has been recommended as an alternative approach for treating intrauterine infections caused by *P. aeruginosa*. Hydrogen peroxide is an oxidizing agent that readily breaks down to release oxygen and water, accompanied by effervescence. Hydrogen peroxide should be used in mares only during estrus.[36]

16.4.7 Tris-aminomethane–EDTA

Intrauterine infusion of tris-aminomethane–EDTA has been reported to result in a degree of inflammation similar to that observed following saline infusion.[37] Tris-aminomethane–EDTA is reported to have a potentiating effect on the antimicrobial activity of a variety of antibiotic and antibacterial solutions.[38] Tris-aminomethane–EDTA may have direct antibacterial effects in some cases and in others may cause a reduction 1053
in the MIC for some organisms in association with particular antibiotics, including penicillin, oxytetracycline, 1054
and gentamicin.

16.4.8 Chlorhexidine Gluconate

Chlorhexidine has been described as being a strong irritant with the potential to cause intrauterine adhesions and therefore has been disregarded for potential uterine therapy.[23] Pony mares have been reported to tolerate uterine infusions of 0.25% chlorhexidine gluconate (Hibitane, Schering-Plough Animal Health, Upper Hutt, New Zealand) with little evidence of irritation onvaginal inspection, whereas dilutions of 0.5%, 1%, and 2% caused severe irritation in a proportion of mares treated.[39] Others have reported that a solution containing 100 µg/ml chlorhexidine gluconate exceeds the MIC for *S. zooepidemicus*, *P. aeruginosa, K. penumoniae, Actinobacillus equuli*, and *Candida albicans*.[40] Infusionof 200 ml of this solution on 3 successive days during estrus had no adverse effect on pregnancy rate when mares were given prostaglandin $F_{2}\alpha$ 8 to 9 days after ovulation and bred at the successive estrus (D. Freeman, personal communication, 1998). More research into the safety and efficacy of chlorhexidine as a uterine therapy is needed.

16.4.9 Dimethyl Sulfoxide

Dimethyl sulfoxide (DMSO) causes an inflammatory response following intrauterine infusion that is similar to other irritants.[30] DMSO infused into the uterus improves endometrial biopsy classification scores by one or more points based largely on reduction of periglandular fibrosis,[36] though others have reported that DMSO did

not have any fibrolytic effect.[30,41] One mare in a treatment group receiving concentrated DMSO subsequently was found to have developed transluminal adhesions.[30] A clinical trial involving intrauterine infusion of DMSO into subfertile mares failed to detect any improvement in fertility following infusion.[36]

16.4.10 Kerosene

Kerosene has been used as an irritant therapy in the equine uterus for many years.[42] Recently, an experimental comparison was performed to evaluate the uterine response in subfertile mares to infusions of kerosene, dilute povidone-iodine, DMSO, and collagenase. The uterine response to kerosene, collagenase, and DMSO was similar, resembling the response after mechanical curettage. Gross and histologic evidence of inflammation had resolved within 14 to 21 days following infusion. Mares treated with kerosene differed from other treatment groups in having improved gland activity on uterine biopsy and higher pregnancy rates following breeding. Nine of 11 (82%) mares conceived, and 5 of 11 (45%) subsequently foaled. Bracher[30] concluded that the increase in secretory activity of the glands observed after intrauterine infusion of kerosene was a major factor in achieving the higher conception and foaling rates.

The standard approach for infusing kerosene involves infusing 50 ml of commercial-grade kerosene into the uterine lumen during diestrus. Diestrus is preferred because the closed cervix is more likely to prevent reflux of kerosene into the vagina with resulting inflammation.[36] Alternatively, one should follow infusions during estrus with digital occlusion of the cervix for a short time to prevent vaginal reflux.

16.4.11 Saline

Saline is useful as a means of flushing or mechanically removing fluid and debris from the uterus and for stimulating the uterus to contract and expel contents. Saline also irritates the endometrium and causes migration of polymorphonuclear leukocytes into the uterine lumen. Warmed saline has been reported to result in rapid and transient enhancement of uterine tone in mares with atonic or atrophic uteri, and saline flushes on day 6 after ovulation have been reported to result in luteolysis via endometrial prostaglandin F release.[8,23]

16.4.12 Plasma

Plasma may be beneficial in mares with chronic and chronic-active endometritis by providing immunoglobulins and complement, both important components in opsonization of bacteria within the uterus.[43] Recent studies suggest that suppression of uterine neutrophil function in susceptible mares is likely to result from the accumulation of fluid, debris, and bacteria that occurs following an underlying failure of uterine mechanical clearance.[44] Treatment and prevention therefore are better aimed at aiding clearance than by infusing plasma. This hypothesis is supported by studies failing to demonstrate any beneficial effect of plasma in susceptible mares.[2,45]

Pascoe[46] recently described a large field study involving the routine postbreeding use of plasma with antibiotics. The pregnancy rate improved significantly when plasma was infused into lactating mares but not in maiden or barren mares. Plasma possibly may be beneficial in foaling mares or in mares that do not have a mechanical clearance problem. Further work is needed to determine factors that may influence the effect of plasma in the uterus of the mare.

Autologous plasma is believed to be preferable to heterologous plasma because of the risk of hypersensitivity, 1054
anaphylaxis, or transfusion illness following heterologous plasma infusion. However, many mares have 1055
received heterologous plasma without problem. Preparation of plasma requires aseptic withdrawal of venous bloodinto heparin-based anticoagulant (typically 5 to 10 units of heparin per milliliter of blood).[3] Complementrapidly degrades at room temperature, and therefore oneshould separate plasma quickly. Gravity sedimentationis acceptable but should be performed under refrigeration. Once separated, one should infuse plasma immediately or stored it frozen in 100-ml aliquots ready forthawing and infusion. One must thaw plasma in warm water or in a microwave on a low setting. Thawingat too high a temperature results in denaturation of protein and loss of immunoglobulin activity. In thefield, preparation of plasma invariably is performed under less than ideal conditions. The author always combines field-derived plasma with a broad-spectrum antibiotic as a uterine infusion to minimize the risk of inadvertently introducing infectious organisms when infusing plasma.

16.4.13 Uterotonics

The importance of mechanical clearance of the uterusin resistance to bacterial infections has been documented clearly, particularly in several recent studies performedby Troedsson and colleagues and LeBlanc and colleagues.[2,6,44,47,48]

Inability physically to clear contaminating material from the uterus within a short period of time now is believed to be the major factor resulting in mares being susceptible to chronic and recurrent uterine bacterial infection.[3] Treatments that assist the uterus physicallyto clear bacteria, fluid, and associated inflammatory by-products and debris from the uterine lumen are critical to the effective treatment and prevention of infectious endometritis. Uterine lavage is effective at removing material from the uterine lumen. Pharmacologic alternatives that induce uterine contractions include oxytocin and prostaglandin $F_2\alpha$ and analogs.

Prostaglandin $F_2\alpha$ or cloprostenol, given by intramuscular injection, causes an increase in intrauterine pressure within 10 minutes, and contractions last for about 5 hours. Oxytocin produces a response within 60 seconds of intravenous administration, but contractions last for only 40 to 60 minutes. Recently, investigators concluded that oxytocin was more effective than prostaglandinin clearing the uterus of colloid. The same study also concluded that cloprostenol was more effective than prostaglandin F or fenprostalene, although all mares treated with prostaglandin analogs did have an increased clearance of radiocolloids.[47] Cloprostenol also has been recommended in favor of dinoprost in mares that have lymphatic stasis. Lymphatics drain particulate matter from the uterine lumen and reabsorb the intramural fluid that accumulates within the uterine wall during estrus. Lymphatics drain dorsally into the vessels in the broad ligament and then into the iliac and aortic lymph nodes. Lymphatic vessels do not contain smooth muscle and therefore must rely on uterine contractions to push fluid dorsally within lymph vessels.[48] One should not administer prostaglandins more than 48 hours after ovulation to minimize the risk of inducing luteal regression.

Concurrent medications may interfere with uterine clearance in susceptible mares. Phenylbutazone and acepromzaine administration have been reported to interfere with clearance of uterine radiocolloid in susceptible mares. The effect is reversed with the administration of oxytocin.[48] Xylazine has been suggested to be a preferable sedative to acepromazine for susceptible mares inthe breeding shed because xylazine causes an increase in uterine pressure. In the event that mares receive acepromazine or phenylbutazone around the time of breeding, one should consider administering oxytocin concurrently to assist in uterine clearance.

Intrauterine administration of uterotonics has received a small amount of study and warrants further work. Intrauterine oxytocin administration has been shown to increase intrauterine pressure but not as much as intramuscular or intravenous administration.[49] Preliminary studies involving the intrauterine administration of10-mg doses of dinoprost suggest it is effective at inducing uterine contractility, but detailed comparative work comparing the effect of uterine versus systemic administration of uterotonics on uterine clearance remains to be completed.[2,50]

The use of oxytocin and prostaglandin (or analogs) as aids for uterine clearance remains empirical. Dosesof between 10 and 25 IU oxytocin have been used toaid mechanical evacuation of the uterus.[51] Information is lacking on the most effective dose, route of administration, and frequency of administration. Little information is available on safety of these products when used around the time of breeding, although both products commonly are used during estrus before and after breeding. In addition, little information is available on practical methods of identifying mares with delayed uterine clearance suitable for application in the field. The presence of uterine fluid detectable by ultrasonography appears to be an indicator of reduced clearance, particularly if fluid persists for more than 6 to 12 hours after mating.[52]

16.4.14 Uterine Lavage

Uterine lavage is a traditional and highly effective method of removing fluid and associated debris from the 1055
lumen of the uterus. Uterine lavage commonly is performed before and after breeding and often is combined 1056
with infusion of antibiotic, antiseptic, or other materialssuch as plasma.[23] In addition, lavage commonly is applied in the early postpartum mare to treat retained placenta or metritis. Emptying the uterus of fluid before antibiotic infusion is likely to improve the efficacy of uterine antibiotic therapy by removing foreign material and inflammatory products from the lumen. Such emptying is likely to be more important for aminoglycoside and polymixin antibiotics that bind to purulent material.[7]

Saline induces an inflammatory response within the uterus. Infusion of acidic saline resulted in an immediate release of endogenous prostaglandin F, whereas infusion of pH-neutral saline did not.[53] Heating the lavage fluid to 45° to 50° C has been reported to result in a rapid and transient increase in uterine contractility.[23]

One normally performs uterine lavage with a Foley catheter or embryo transfer catheter with a large balloon cuff (75 ml). One infuses fluid until the uterus is distended (500 to 1000 ml), removes it by gravity flow, and collects it in a vessel to allow measurement of lavage and recovered volumes and the appearance of the recovered fluid. The opacity of the recovered fluid indicates the degree of inflammation present within the uterus and guides the need for additional flushing. One should repeat lavage until the recovered fluid is clear. Apparently, no controlled studies document the efficacy of lavage as a treatment modality for endometritis.

16.4.15 General Treatment Strategies for Management of Uterine Disease

Successful treatment of acute or chronic infectious endometritis is based on elimination of the causative organism, reduction of any accompanying inflammation, correction of anatomic defects, and prevention of recurrence. One must correct predisposing anatomic causes of endometritis such as poor vulval conformation, cervical or rectovestibular lacerations, and urine pooling surgically before applying therapies aimed at resolvingan endometritis. The most common routine procedure performed on broodmares is Caslick surgery.

One should perform more extensive surgical procedures during the non–breeding season to allow the mare time to recover before breeding.

The approach to uterine therapy depends on the diagnosis and presenting clinical signs. One manages infectious endometritis by eliminating fluid and debris from the uterine lumen by lavage and administration of a uterotonic, followed by uterine infusion of a topical treatment (antibiotic, antifungal, antiseptic, etc.). Choice of uterine therapy, formulation, dose, volume infused, diluent, and treatment frequency are discussed elsewhere in this chapter. Lavage of the uterus on subsequent treatment visits is only necessary if the uterine lumen continues to accumulate fluid or if one is performing the lavage to stimulate uterine contractility.

Many treatments have been suggested for chronic degenerative endometritis (endometrosis), but consistently favorable results have not been reported. All of the techniques and treatments described for acute and chronic endometritis have been used. In addition, mechanical and chemical curettage or irritant therapy is commonly used in mares with this condition. Regardless ofthe treatment, the prognosis is considered to be poor,[3] with the exception of those mares that improve from a pretreatment grade III biopsy to a posttreatment grade II biopsy classification.[54]

Topical treatment of the uterus must be accompanied by strict attention to hygiene. One must pay attention to management principles to achieve successful resolution of endometritis accompanied by a reduced risk of recurrence and an optimal opportunity for pregnancy.[7]

16.4.16 Postmating Endometritis

An area in which important advances have been made in the past several years is in understanding and management of postmating endometritis. A transient and physiologic endometritis occurs after breeding because of the intrauterine deposition of semen. In normal, fertile (resistant) mares this transient inflammation resolves within 36 hours after mating. Contamination and inflammation of the uterus following breeding has to be resolved before the embryo enters the uterine lumen at about 6 days after ovulation in the pregnant mare. Impaired physical clearance of bacteria, fluid, and inflammatory products is considered to be the primary factor responsible for susceptibility to persistent, infectious endometritis.[3] One should examine mares in early estrus using ultrasonography to evaluate the presence and echotexture of uterine luminal fluid. Presence of large volumes of echogenic fluid indicates acute endometritis, and one may prefer to treat such mares aggressively through estrus and shorten the cycle to aim for breeding on the successive estrus. One can remove large volumes of anechoic fluid in early estrus using uterine lavage with saline, followed by injection of oxytocin to prevent fluid accumulation from recurring. One may manage smallto moderate volumes of fluid using oxytocin alone. One should examine mares 20 minutes after administrationof oxytocin to ensure uterine fluid has been expelled;in some cases, manual dilation of the cervix is neededto facilitate effective expulsion of fluid. One may use intrauterine infusion of antibiotic in early estrus in an attempt to eliminate endometritis or reduce the 1056
risk of endometritis before breeding. Any product used for uterine lavage or instillation in the prebreeding or 1057
postbreeding estrous period should have minimal irritating effect on the endometrium. Physiologic saline, Dulbecco's phosphate buffered saline, and lactated Ringer's solution are believed to be associated with less inflammatory response than water. One should choose antibiotics with care and not use antiseptics or irritants at all in this period. One may continue to perform ultrasound examinations through estrus right up to immediately before breeding, with the goal being to eliminate fluid from the lumen of the uterus before breeding.

Clinicians generally agree that mares should be bred once only to minimize contamination of the uterus and genital tract. One should consider the use of ovulation induction agents (human chorionic gonadotropin or

synthetic gonadotropin-releasing hormone) routine for susceptible mares because these agents greatly improve the likelihood of a single breeding per ovulatory cycle. Normal practice is to aim for a single breeding in the time period from 24 hours before ovulation to 12 hours after ovulation. Depending on stallion fertility, mares may be bred as early as 48 to 72 hours before ovulation without reduction in fertility. Recently, Pycock has proposed that susceptible mares be bred only once, at least 24 hours before ovulation and perhaps earlier, assuming suitable stallion fertility.[55] Breeding at this time ensures that any contamination associated with breeding occurs when circulating estrogen concentrations are maximal, progesterone concentrations are minimal, uterine defense mechanisms and physical drainage should be optimal, and more time is available after breeding to implement uterine therapy before progesterone rises and the cervix begins to close after ovulation. If breeding is by artificial insemination, one should add a semen extender containing antibiotic to the ejaculate and allow the extended semen to stand undisturbed for a minimum of 15 minutes to allow elimination of possible pathogens from the ejaculate. One also may infuse antibiotic-containing semen extender into the uterus of the mare immediately before natural breeding in an attempt to obtain a similar effect. One should examine susceptible mares by ultrasoundas early as 4 hours after breeding and preferably before12 hours, again to check for accumulation of fluid.[35] Examination ensures that one can eliminate uterine fluid using lavage or uterotonics or a combination of these treatments before the development of an inflammatory response or proliferation of potentially pathogenic organisms. One infuses into the uterus a broad-spectrum antibiotic about 20 minutes after administration of uterotonic. Pycock suggests using a small-volume infusion (30 ml) for the postbreeding treatment because susceptible mares are expected to have clearance problems.[55] Administration of oxytocin can continue, and one can examine the mare the following day to ensure that uterine fluid is not accumulating. If fluid is still present, one can repeat the treatment approach (lavage, uterotonic, and infusion). One should not continue intrauterine treatment past day 3 after ovulation to minimize the risk of endometrial inflammation persisting past day 5 or 6 when an embryo may be expected to be entering the uterus. One should not administer uterotonics past about day 2 after ovulation because the cervix generally is starting to close, thus inhibiting uterine drainage. One should use prostaglandins with care after ovulation because of the added risk of possible induction of luteal regression. The use of a single postbreeding uterine infusion ofa broad-spectrum antibiotic combined with uterotonic administration has been reported to result in higher pregnancy rates in field trials than an antibiotic or uterotonic alone.[56]

The combination of prebreeding and early postbreeding estral management, with the use of oxytocin, has improved the ability to prepare an optimal uterine environment greatly for breeding and for establishmentof early pregnancy. The use of systemic antibiotics and nonsteroidal antiinflammatory drugs in susceptible mares after breeding has been suggested anecdotally as offering promise in reducing the risk of establishment of endometritis and endometrial prostaglandin release.[57,58] Such therapies remain unproven.

16.5

16.5—Hormonal Manipulationof the Mare

Elizabeth Metcalf

Veterinarians attempt to mimic or change the physiology or behavior of the mare through the administration of exogenous hormones. This chapter examines the effects of hormonal preparations administered to mares in an attempt to enhance their reproductive efficiency.

16.5.1 Vernal Transition

As day length increases, nonpregnant mares gradually emerge from a state of ovarian quiescence to regular cyclicity. Through the hypothalamic-pineal-pituitary-ovarian axis, mares begin to show clinical signs of a prolonged estrous period followed at last by the first ovulation of the season. Section 16.1 presents more precise physiologic events of this period.

Many hormonal regimens aimed at shortening the interval to first ovulation have been examined. Increasing the exposure of a mare to light from 6 A.M. to 10 P.M. has proved a potent and effective means of shortening the time to first ovulation of the season. In an attempt to hasten the interval further, researchers have examined other hormonal preparations including melatonin,[1] progestins[2] (plus estrogens),[3] and dopamine antagonists such as domperidone[4,5] and perphenazine.[6] Intravaginal inserts containing progesterone also have been successful in induction of cyclicity in anestrous mares.[7] Although many of these results are promising, progestin therapy is used most widely. One should note that providing good nutrition, especially in aged mares, may hasten the onset of the first ovulation,[8] possibly by involving hormones that are associated with digestive metabolism.

16.5.2 Synchronizing the Estrous Cycle

In the attempt to optimize breeding efficiency, the ability to predict estrus and ovulation becomes an important management tool. Unfortunately, mares vary more in response to hormonal treatment than ruminant species do. Thus the bovine concept of fixed-timed insemination has not been applicable in equine reproduction. The objective of most attempts to manipulate the timingof the estrous cycle of the mare is synchronization ofa group of mares (e.g., in an embryo transfer program) or more commonly strategic management of insemination with shipped or frozen semen.

To manipulate the estrous cycle of the mare with some precision, one must understand the basic endocrine events of the normal 21- to 22-day cycle of the mare.[9] The day of ovulation is considered to be day 0 and is preceded by a period of estrogen domination (5 to 7 days). The high estrogen levels are responsible for the signsof behavioral estrus and cause the palpably decreased tone of the uterus and cervix. Under the influence ofthis estrogen-priming, a cascade of preovulatory events occurs in the hypothalamic-pituitary axis, and the prolonged increase in luteinizing hormone (LH) blood levels ultimately results in ovulation. The diestrous phase is dominated by progesterone secretion from the corpus luteum. This diestrous phase lasts for 14 to 16 days. In the absence of maternal recognition of a pregnancy, endometrial prostaglandin $F_2\alpha$ ($PGF_2\alpha$) surges—possibly stimulated by or at least coordinated with oxytocin—cause luteolysis and regression of the corpus luteum. Concomitant with the decline in progesterone, estrogen levels begin to rise as a new cohort of follicles develops.

Most hormone regimens aim at manipulating the luteal phase of the cycle. Perhaps the simplest method of synchronizing the cycle of a mare is by using synthetic preparations of $PGF_2\alpha$, which effectively and reliably may shorten the cycle of the mare if used after the corpus luteum is well-formed—after day 5 to 6 of the cycle. The mare returns to estrus within 3 to 5 days following administration of $PGF_2\alpha$ and subsequent regression of 1059

the corpus luteum. Depending on the structures present on her ovary at the time of administration, the mare ovulates approximately 7 days later.[10] Although administration of $PGF_2\alpha$ before day 5 is usually ineffective in returning a mare to estrus, treatment of mares with a $PGF_2\alpha$ analog on day 0 (ovulation) or day 1 still does affect the developing corpus luteum. A transient but significant suppression in progesterone levels occurs, with less echogenicity and size of the corpus luteum and decreased subsequent pregnancy rates.[11,12]

A number of $PGF_2\alpha$ preparations have been used successfully in mares; however, they are associated with many undesirable side effects including profuse sweating, anxiety, diarrhea, and signs of colic. The severity of the side effects depends on the preparation of $PGF_2\alpha$ andthe susceptibility of the individual mare. Cloprostenol (Estrumate, Bayer Corp., Shawnee, Kansas) administered at lower doses (250 μg) usually is associated with fewer side effects than the less expensive analog, dinoprost tromethamine (Lutalyse, Upjohn Co., Kalamazoo, Michigan) when administered intramuscularly. The absence of side effects is *not* related to the effectiveness of the drug in inducing luteolysis.

Treatment with progestins represents one of the oldest and most reliable means of synchronizing estrus in the mare, especially when coupled with appropriate light exposure and $PGF_2\alpha$ administration. Progestins simulate the diestrous period of the estrous cycle. Repositol progesterone (not commercially available), progesterone in oil (Sigma Chemical Co., St. Louis), or oral progestin compounds (altrenogest [Regumate, Intervet Inc. Millsboro, Delaware]) are effective in suppressing estrous behavior but not necessarily ovulation. Treatment is only effective in synchronizing mares that are transitioning into regular cyclicity or are cycling regularly; treatment is not effective in mares that remain in seasonal anestrus. Therefore examining the reproductive tract of the mare by transrectal palpation and ultrasound before initiating treatment is prudent. Ovaries in anestrous mares feel smooth, firm, and small on palpation. Any follicles are small, usually less than 10 mm in size on the ultrasound examination. Conversely, mares that are ready to begin regular cycles or are cycling regularly have larger, irregular-shaped ovaries of variable firmness with multiple follicles greater than 10 mm in diameter. One may image a corpus luteum with ultrasound.

Even though the drug is more expensive, the oral progestin preparation altrenogest perhaps remains the most popular progestin compound to use in mares. Altrenogest is easy to administer, is nonpainful, and has few side effects. Fillies born to mares treated with altrenogest may reach puberty earlier than fillies from nontreated mares and rarely are born with transiently enlarged clitorides.

One should use all progestin preparations with some caution in mares that are susceptible to delayed uterine clearance or uterine infections, for several reasons. Progestins increase the tone of the cervix, and their use may inhibit the physical clearance of fluid. Progestins also have been associated with lower immunoglobulins levels (especially IgG) in the uterus.[13] The combination of these side effects ultimately can lead to delayed uterine clearance, endometritis, pyometra, etc.; therefore, during treatment, one should monitor mares susceptible to these conditions.

When synchronizing mares, one recommendationis that progestins be used for a minimum of 10 daysin cycling mares and 14 days in transitional mares. On the last day of progestin treatment one may give a $PGF_2\alpha$ injection to lyse any remaining corpora lutea. Time to ovulation depends on the structures that are present at the end of progestin administration. The mare should return to estrus in 3 to 5 days and on average, ovulation occurs by 7 days after treatment.

16.5.3 Synchronizing Ovulation

A number of agents that shorten the interval to ovulation in the mare have been used to synchronize the cycles further. The most effective agents possess LH activity with varying degrees of follicle-stimulating hormone (FSH) activity. Human chorionic gonadotropin (hCG [HCG, Intervet]), with its potent LH-like activity, is at the time the least expensive and perhaps the most popular agent used for the induction of ovulation. Human chorionic gonadotropin has been reported to be effective at doses ranging from 1000 to 5000 IU given intramuscularly, intravenously, or subcutaneously.[14]

Use of hCG in the mare has some limitations. First, with its repeated use, antibody development has been documented in several studies[15]; however, the clinical impression of many practitioners is not in agreement with these studies. Secondly, mare owners often complain about the apparent pain associated with administration of some hCG products. Finally, the reliability of hCG in its ability to hasten the interval to ovulation, especiallyin the older or compromised mare, has been questioned. Regardless of its potential disadvantages, hCG remainsa popular, inexpensive, and effective means of inducing ovulation in most mares.

Synthetic gonadotropin-releasing hormone analogs also have proved to be effective in inducing ovulation (deslorelin acetate [Ovuplant, Fort Dodge, Iowa]; and buserelin [Buserelin, Intervet; not commercially available in the United States]).[14,16,17] Although the use ofthese latter agents may delay the return to estrus by 1 to 2 days 1060
if the mare fails to conceive, the general impression of practitioners is that because these gonadotropin- 1061
releasing hormone analogs are more reliable in inducing ovulation, especially in mares that are more prone to ovulation failure (older mares, mares in vernal transition, mares concomitantly treated with prostaglandin inhibiting agents such as many antiinflammatory drugs), the advantages far outweigh the disadvantages of choosing this drug. Furthermore, removal of the implant a few days following insertion can ameliorate this delay.[18]

Ovulation induction agents are more reliable and effective if given at the appropriate time during estrus. If endometrial folds are apparent on the ultrasound examination, and a dominant softening follicle is present, usually greater than 30 mm in diameter, then hCG, deslorelin acetate, and buserelin are expected to induce ovulation an average of 36, 41 to 48,[14] and 24 to48[17] hours, respectively, following administration. Samper reported that 98% of mares with maximal endometrial edema given hCG or deslorelin consistently ovulated within 48 hours of administration.[19] Most remarkably, most mares to which Ovuplant has been administeredat the proper time, ovulate 38 ± 2 hours later,[20] truly allowing appointment breeding.

16.5.4 Synchronizing Estrus and Ovulation

One can use progestins along with estradiol-17β (P+, Franck's Veterinary Pharmacy, Des Moines, Iowa) to obtain greater synchrony between mares. Although not commercially available, biodegradable microspheres impregnated with progesterone (1.25 g) and estradiol (100 mg) also have been used to synchronize the estrous cycle of the mare[21–23]; they appear to suppress follicular development and ovulation. However, these drugs have been replaced to some extent by intravaginal devices (CIDR-B, InterAg, Hamilton, New Zealand) that contain progesterone; one administers estradiol (10 mg) at the time of insertion. Administration of a $PGF_2\alpha$ analog is advised at the time of insert removal (12 to 14 days). Finally, one uses a deslorelin implant when the dominant follicle reaches a size of 40 mm. This regimen nicely synchronizes ovulation and estrus[24]; however, neither these intravaginal devices nor the encapsulated microspheres currently are licensed for horses.

16.5.5 Delaying Estrus and Ovulation

Although most hormonal regimens act to hasten the interval to estrus, numerous managerial reasons to delay estrus exist as well. Altrenogest originally was designed to prevent show mares from exhibiting estrous behavior, and it has proved to be effective in this regard, suppressing signs of estrus in 95% of mares that were given a daily dose of 0.044 mg/kg for 3 days.[25] Although reports represent only anecdotal testimony, many horses owners have found that altrenogest not only is effective at estrus suppression but also appears to exert a calming effecton horses.

In an attempt to find a more economic and less time-consuming means of suppressing estrous behavior in their mares, progestin/estradiol implants (Synovex, Syntex Animal Health, Des Moines, Iowa) licensed for food animals have been investigated in mares. Although mare owners often report an improvement in the behavior of the mare, scientific reports have been less supportive of their use. McCue, Lemons, Squires, et al.[26] found that mares treated with these implants, even at 20 times the usual dose, did not show suppression of estrous behavior and cylicity.

Altrenogest recently has been tested for its effectsin delaying ovulation after the mare is in estrus. Theoretically, if the LH surge has not occurred yet, oral progestin treatment should inhibit LH and delay ovulation. Altrenogest at label dose or 2 times the label dose is effective in delaying ovulation compared with control mares as long as an ovulation-induction agent has not been administered.[27] Intraluminal fluid retention, probably caused by increased cervical tone, has been witnessedin some mares. Although this application is promising, one should intrepret these results with caution, because treated mares had lower pregnancy rates (though not statistically significant).

Delaying the interval to first ovulation of recently foaled mares results in higher pregnancy rates for the first heat cycle. Although the natural foal heat of a mare may be highly fertile, many early pregnancies are lost, likely because of an adverse uterine environment. To optimize the maintenance of those early pregnancies and yet still increase the reproductive efficiency of the mare by breeding her back as soon as possible, delay of the first postpartum interval to ovulation using a combinationof progesterone and estradiol-17β (E2-17B, Sigma Chemical) in oil is beneficial. In an attempt to increase the fertility of foal-heat breeding, Sexton and Bristol[28] reported that this protocol successfully delays the postpartum interval to first ovulation, thereby increasing the period of time for uterine involution and pregnancy rate.

16.5.6 Superovulation

In efforts to increase the number of offspring produced in the lifetime of a mare or in any given season, researchers have investigated numerous means of superovulating mares. Overall, attempts to cause mares to superovulate reliably and effectively have been disappointing. The increased numbers of ovulations/embryos have been minimal or pregnancy rates have been low. The administration of porcine FSH preparations is 1061
ineffective in mares, except at cost-prohibitive doses.[29] Stimulation of endogenous FSH secretion by indirect 1062
and direct immunization against inhibin has not resulted in a superovulatory responsein mares.[30] The administration of equine pituitary extract preparations in research trials only increases the number of embryos recovered from 0.5 per cycle to 2.2 per cycle.[31,32] Purified equine FSH has failed to increase the numbers of ovulations or recovered embryos compared with equine pituitary extract.[33]

16.5.7 Teaser Mares

Breeding facilities require at least one mare exhibiting behavioral estrus to be able to collect semen from most stallions. Some stallions appear to prefer a particular mare or a certain color of mare and therefore a varietyof mares in heat is sometimes desirable for ease of collection. Thus use of exogenous hormone regulation to encourage a mare to display signs of estrous behavior often becomes necessary.

One strategy for ensuring the availability of a teaser mare is to have a rotating supply of mares thatare constantly short-cycled with $PGF_2\alpha$ analogs. If one injects the mare with $PGF_2\alpha$ 5 days after the cessation of behavioral estrus, in theory she will return to heat in a few days because the mature corpus luteum on her ovary will be lysed by the injection. Ideally, a minimum of two teaser mares suffices for this program. An additional benefit is that the fertility of the mare is unaffected by the prostaglandins.

Administration of estrogen compounds also causes some mares to exhibit estrous behavior. Estradiol cypionate (ECP, Upjohn), a long-acting estrogen, and estradiol-17β, a shorter-acting estrogen have been investigated; the results of administration of either compound vary, especially over time and in particular with estradiol cypionate. The estrogen compounds are far more effective in ovariectomized mares than in intact mares, because even the smallest amount of progestin secretion from the ovary inhibit signs of behavioral estrus. Interestingly, ovariectomized mares often demonstrate low-grade signs of heat even in the absence of exogenous hormonal administration. Theoretically, these signs are caused by the absence of ovarian progesterone and the continued secretion of estrogens from other sources, particularly the adrenal glands. Moreover, even the smallest amounts of circulating estrogens are postulated to cause some mares to show constant signs of estrus in the presence of a stallion. The responseof ovariectomized mares to exogenous estradiol-17β or estradiol cypionate has not been reliable, especially with administration of these hormones in increasing amounts and frequency. The hormones appear to reach a threshold at which the clinical response actually is contrary to the signs expected, and treated mares actually may show increased aggressiveness to stallions. Low doses (1 mg intramuscularly) of estradiol cypionate, given every 2 to3 weeks, appear to be most effective in preserving the ovariectimized teaser mares for many years of service. Old, anestrous mares often function as ideal teaser mares for some stallions. In the absence of functional ovarian secretion, the low levels of circulating estrogens may cause a mare to exhibit signs of estrous behavior continually. Unfortunately, a number of stallions appear uninterested in these old mares despite their overt display of heat.

16.5.8 Maintenance of Pregnancy

Although the mechanism is unknown, progesterone supplementation in the form of injectable or oral preparations often is used to maintain pregnancy at all stages of gestation. The well-accepted fact is that early pregnancy maintenance in the mare requires the function first of the primary corpus luteum (approximately 45 days) and second of the accessory corpora lutea (45 to 90 days or more). Still, some mares appear to require progesterone supplementation during this period; otherwise, they lose the pregnancy. Hormonal assays can be confusing because progestin levels in these mares may appear well within the normal range for mares that do not appear to require supplementation.

Some mares also appear to require progesterone supplementation for maintenance of pregnancy in the later stages of gestation as well. Altrenogest may be effective in preserving the pregnancy in a compromised mare. In an experiment that examined the maintenance of pregnancy in mares suffering from experimentally induced endotoxemia, Daels, Besognet, Hansen, et al.[34] demonstrated that mares treated with altrenogest administered

at 2 times the recommended dosage suffered significantly less pregnancy loss than the untreated mares. Pregnancy loss rates appear higher in the Miniature horse mare (25%)[35] than those reported in larger breeds (<10%).[36] Moreover, unlike reports of studies on larger breeds, most of the pregnancy loss in the Miniature horse mare occurs during late term.[35] Thus many Miniature horse mares receive supplemental progesterone for the duration of their pregnancy. Speculation is that placental insufficiency may contribute to the increased loss of pregnancy in this breed, because the size of the foal often is larger with respect to its dam than in the larger breeds of horses.

16.5.9 Endometritis

Mating-induced endometritis is regarded as a normal transient physiologic event in the mare in response to sperm deposited in the uterus.[37] However, some mares are susceptible to a delay in uterine clearance, especially older, multiparous mares in which the uterus lies well beneath the pelvic brim.[38] Warm saline lavage followed 1062

by small doses of oxytocin (Oxytocin Injection, Vedco, St. Joseph, Missouri; intramuscular or intravenous)[39,40] 1063
are especially beneficial in these susceptible mares. The response to oxytocin appears to be greatest with administration just before ovulation, and this preovulatory insemination results in higher pregnancy rates.[41–45] Rigby, Hill, Miller, et al.[46] have reported that administrationof exogenous oxytocin to mares immediately following insemination does not improve pregnancy rates and that certainly this approach is not required for all breedings. Those mares with delay in uterine clearance in which intraluminal fluid remains or recurs despite multiple small doses of oxytocin may respond to $PGF_2\alpha$ therapy. Prostaglandin exerts a more sustained effect on uterine myometrial activity than oxytocin and thus may promote uterine evacuation and enhanced lymphatic drainage in difficult cases.[47]

16.5.10 Cervical Dilation

One of the most frustrating conditions encountered when breeding mares is failure of cervical dilation during estrus. On transrectal palpation, the cervix may feel toned, instead of “melted,” as it should during estrus just before ovulation. Because previous damage to the cervix and the subsequent formation of adhesions can presenta similar and confusing picture of failure of cervical relaxation, a thorough visual and manual cervical examination is prudent. In maiden mares, inserting a finger through the cervix to act as a guide for the insemination pipette is often difficult. Although this condition does not prevent artificial insemination, it can prevent not only penetration of the cervix by the penis of the stallion but also the normal evacuation of fluid in the hours following breeding, thereby setting the stage for delay in uterine clearance and persistent endometritis. Although not objectively studied, this condition does appear to affect older maiden mares more commonly. However, even normal maiden mares often do not have the same degree of cervical relaxation during estrus that is typical of pluriparous mares. A synthetic PGE_1 analog, misoprostol (Cytotek, Searle Corp., Chicago, Illinois), has been used successfully in women for cervical dilation. This compound has not yet been evaluated objectively in horses and currently is not approved for veterinary use. However, many clinicians have seen some encouraging results, simply by covering the external cervix with PGE_1 cream several hours before cervical dilation is desired. If only PGE_1 tablets are available, practitioners have crushed 1 to 2 tablets (200 μg) and mixed them with a small amountof sterile lubricant before application. Finally, digital insertion of a tablet into the external cervical os may be effective as well. Occasionally, veterinarians have used this preparation combined with other parturition induction agents if attempting to terminate a pregnancy prematurely. Again, only anecdotal reports of efficacy currently exist.

16.5.11 Oviductal and Uterine Contraction

The early embryo secretes PGE_2, which is believed to play a role in the contractility of smooth muscle of the oviduct and thus to promote propulsion of the embryo through the oviduct.[48] Prostaglanding E_2 also is secreted during the high mobility phase of the embryo and is suspected to stimulate uterine contraction and enhance uterine tone.[49] Laparoscopic application of PGE_2 along the serosal surface of the oviduct can modify embryo transport. Interestingly, not only is embryo transport hastened, but also unfertilized oocytes that are rarely recovered in the mare are transported to the uterus.[50]

The addition of PGE_2 to semen just before artificial insemination has increased pregnancy rates in mares bred with a fertile semen but not with a subfertile semen.[51] These results are disappointing because the addition of PGE_2 to semen has been associated with higher fertility rates in other species.[52,53] Furthermore, the role of PGE_2 at the uterotubal junction of the mare has been speculated to affect spermatozoal selection. Selection is believed to be based on morphology, but motility of the spermatozoa may play a larger role in this selection process than once suspected. Selection is an area of research that deserves continuing attention.

16.5.12 Future Use of Hormones

Many of the hormone preparations discussed were not designed for use in the mare and they may not be available commercially. Still, great strides have been made in manipulating the endocrine environment to enhance pregnancy rates, at least partially because of the growing artificial insemination industry. Manipulation of the hormonal milieu of the broodmare allows regulationof the estrous period, promotes prediction of ovulation, enhances the reliability of ovulation, and prepares the uterine environment for the maintenance of pregnancy. If per cycle pregnancy rates can be enhanced, then this regulation represents an economically sound investment to owners and veterinarians. Owners have more offspring in a shorter amount of time and lower veterinary costs, and veterinarians have time to use optimal management in breeding more mares.

16.6—Breeding Management to Optimize Pregnancy Rates

Elizabeth Metcalf

Where foals once were born only as a result of natural field breeding, the art and science of modern horse breeding has continued to expand its innovative techniques to keep pace with advances in reproduction. Now foals are born as a result of more advanced procedures that include artificial insemination, oocyte transfer, embryo transfer, embryo splitting, intracytoplasmic sperm injection, gender selection, and in the future, cloning from a single cell. Furthermore, through improvements in cryogenic techniques, gametes and embryos may be preserved indefinitely. Veterinarians and scientists function primarily as facilitators of these processes that serve to preserve and perpetuate valuable genetic lines. The following sections examine the procedures currently used in equine private practice to facilitate the inseminationof horses.

Although increasing the number of pregnancies produced per mare in a given year is possible through the techniques of embryo and oocyte transfer, pregnancy rates per cycle have not improved significantly from field breeding to artificial insemination. In the past decade, many changes have been implimented in breeding facilities and include (but are not limited to) the housing ofmares and stallions, the methods used for teasing mares and

stallions, the design of the breeding shed, stallion and mare handling techniques, promoting appropriate behavior in the breeding shed, the processing of stallion semen, and the management of the mare population.

In an attempt to mimic the physical and physiologic events that occur in nature, breeders must understand not only equine behavior but also the processes of intromission, ejaculation, and eventually fertilization of the oocyte.

Although natural and artificial insemination of the mare entail deposition of semen within the uterus of the mare, natural service invokes several physiologic processes that are absent in artificial insemination.[1] When the penis of the stallion enters the vagina of the mare, several rhythmic pelvis thrusts occur before ejaculation directly into the uterine body. Not only does this action cause rapid vasodilation of blood vessels that supply the corpus spongiosum penis, resulting in the characteristic "belling" of the glans penis, but also it stimulates strong uterine contractions that in turn propel the deposited sperm toward the oviductal papillae of the mare. The engorged glans penis also may function to prevent the immediate backflow of semen during ejaculation. On completion of ejaculation, detumescense of the penis follows and the mare moves forward out from under the stallion. This sequence of events may occur many times on a given day under natural conditions.

Fertilization of the oocyte in the mare takes place in the ampulla of the oviduct. Before this, the spermatozoa must undergo capacitation and the acrosome reaction, a complex series of events that results in remodeling of the sperm plasma membrane and release of specific enzymes that enable the sperm to penetrate the oocyte. Although one 1065
can recover capacitated sperm from the uterus of the mare, uncapacitated sperm[2,3] are selected[4] to reside in the 1066
isthmus of the oviduct until the oocyte is present. Spermatozoa actually bind to oviductal epithelial cells, a process that appears to be enhanced in estrous mares but not in diestrous mares.[5] Abnormalities of this process may contribute to the subfertility of the mare or the stallion.

Mares with poor fertility have fewer sperm residingin the storage sites of the oviduct.[6] Furthermore, stallions with poor fertility may have spermatozoa with inherent damage that prevents them from being selected to reside in the oviduct. The effect of this damage more likely is caused by poor binding capacity rather than poor motility or reduced sperm transport.[3] Spermatozoa have the ability to survive in oviductal cell culture for at least 6 days.[7] This supports the report of a mare that became pregnant after a single mating 7 days before ovulation[8] and the studyby Woods, Bergfelt, and Ginther[9] in which mares were bred successfully more than 6 days before ovulation. Conversely, an oocyte is viable in the oviduct for only a short time, perhaps as little as 12 hours,[10] as indicated by the low pregnancy rates of mares bred more than 12 hours after ovulation.[9,11,12] Capacitated spermatozoa therefore must be available for successful fertilization.

Before any type of insemination, assessment of fertility of the mare and stallion is advisable. Many tests are available that evaluate fertility of stallion semen, but the most informative measure is the per cycle conception or foaling rate. Although no single in vitro laboratory test has proved to correlate precisely with stallion fertility, stallions with semen that demonstrates a high percentage of morphologically normal, progressively motile spermatozoa with little reduction in motility over the first24 hours of storage often prove to have better fertility than those with semen that lacks these attributes. Other means of predicting stallion fertility with in vitro tests include flow cytometric analysis of sperm membranes, organelles, and DNA; computer-assisted motility analysis; membrane "stress" tests; glass wool–Sephadex bead filtration; binding and penetration assays; and antisperm antibody assays (see discussion elsewhere in this chapter). Unfortunately, because of the expense, most stallion semen is not evaluated routinely by such sophisticated testing. Thus the reproductive history of the stallion becomes most important in predicting future fertility.

One also should evaluate the fertility of the mare. Too often the mare is selected as a broodmare candidate simply because of her availability. One should performa breeding soundness examination based on her age, history, and parity. The breeding soundness examination may range from a rectal and ultrasonographic examination of the reproductive tract to a cytologic testing, culture, and biopsy of the endometrium to a videoendoscopic examination of the endometrium. Inclusion of an ultrasound examination at every rectal examination not only enhances the continual education of the veterinarian but also aids in detection of many unpalpable changes. Most importantly, ultrasound examination ultimately enhances breeding efficiency and pregnancy rates by using the most sophisticated tools available.

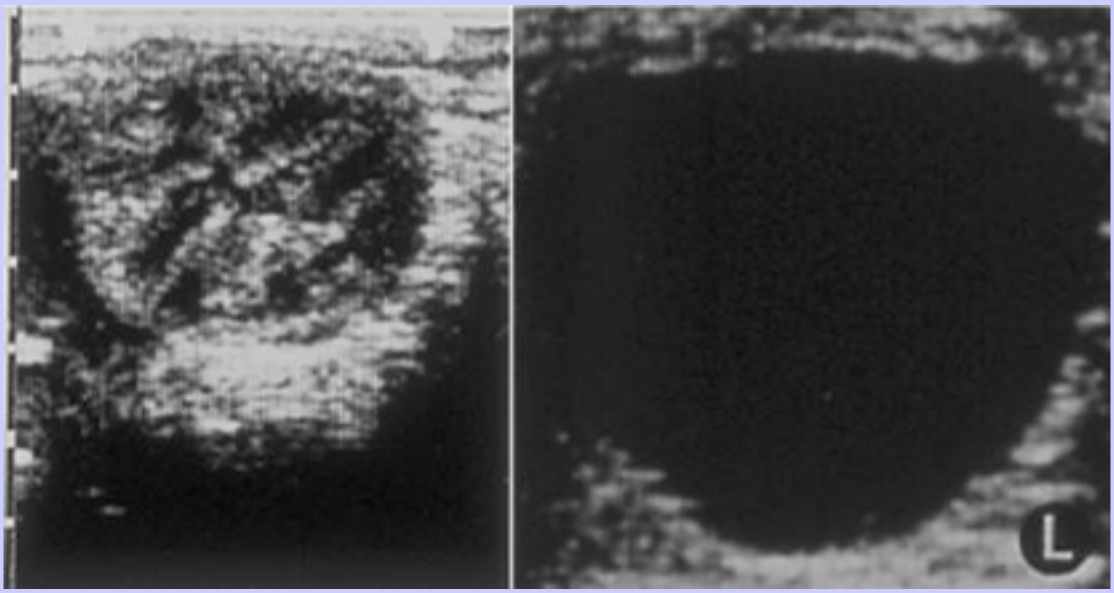
16.6.1 Preparation of the Mare for Breeding

The ultimate goal of insemination is to provide semen in a time frame that coordinates the availability of capacitated spermatozoa with the arrival of the transported oocyte within the oviduct of the mare. Therefore the timing of insemination with ovulation is critical.

One should examine mares in heat daily. During the estrous phase of the heat cycle, one performs an ultrasound examination of the reproductive tract to support and enhance the results of the rectal examination. The appearance of a dominant, growing follicle and the classic spoke-wheel pattern of endometrial edema, which one may quantify subjectively,[13] indicate pending ovulation (Figure 16.6-1). The ultrasound examination also may demonstrate the presence of echogenic particles within the follicle and increasing echogenicity of its wall, both of which indicate impending ovulation within the next 24 hours.[14] Finally, detection of a drop in follicular pressure by measuring transrectal tonometry is even possible and indicates pending ovulation.[15] Although the duration of heat in the mare may vary, most mares ovulate near the end of this estrous phase.[16] This follicular edema is less apparent on ultrasound examination just before ovulation. Because the timing of insemination with ovulation is so critical, the presence or absence of this edema can be a powerful tool to optimize pregnancy rates through the control of ovulation timing.

A number of agents are available that effectivelyshorten the interval to ovulation.[17–20] These agents includehuman chorionic gonadotropin and gonadotropin-releasing hormone analogs (see the discussion of hormonal manipulation in Section 16.5). These induction agents are reliable and effective if given at the appropriate time during estrus. If endometrial folds are apparent on the ultrasound examination and a dominant softening follicle is present, usually greater than 30 mm in diameter, one can expect human chorionic gonadotropin (HCG Intervet, Millsboro, Delaware), deslorelin acetate (Ovuplant, 2.2 mg; Fort Dodge, Iowa), and buserelin (Buserelin, Intervet, Millsboro, Delaware [not commercially available in the United States]) to hasten ovulation on average of 36,[17] 41 to 48,[17] and 24 to 48[13,18,21] hours, respectively, following administration. However, some disadvantages are associated with the use of deslorelin acetate. McCue, Farquhar, and Squires[22] have reported that in mares treated with deslorelin acetate, the interestrous interval may 1066
be prolonged on the average by 2 days because of a diestrous inhibition of pituitary follicle-stimulating 1067
hormone secretion. Removal of the implant at 2 days after administration appears to prevent the delay in return to estrus.

Figure 16.6-1 The appearance of a dominant, growing, softening follicle *(right)* and the classic spoke-wheel pattern of endometrial edema *(left)* indicate pending ovulation. (From Ginther OJ: *Reproductive biology of the mare*, ed 2, Cross Plains, Wis, 1992, Equiservices.)



16.6.2

Pasture Breeding

Successful pasture breeding requires an understandingof equine social structure. Every time a new memberis introduced to the herd, disruption of the social strata and a reorganization of the ranking occur. Theoretically, optimal field breeding management aims for a closed herd to minimize stress and enhance breeding efficiency.

Under field conditions, mares in heat approach the stallion for teasing. If interested, a stallion may mount a mare numerous times with or without an erection, with or without copulation, and most interestingly, with or without ejaculation. This behavior rarely is sanctioned in breeding facilities, often leading to undesirable behavior in breeding stock.

16.6.3

Breeding in Hand

Many breeding facilities continue to breed their stallions in hand, especially if the stallions belong to registries that do not allow registration of foals produced by artificial insemination. One perceived advantage to this management practice is that it may require fewer personnelor less time to breed the mare and therefore is more cost-efficient. However, this is not usually the case, for in-hand breeding poses far more risk to the mare, stallion, and handlers and therefore requires more personnelto ensure the safety of all involved. In-hand breeding also may require far more preparation of the mare than artificial insemination, especially in applying

restraining devices or removal of the foal for breeding. Thereforein-hand breeding does not necessarily reduce the time needed to breed a mare, especially if the cover does not go as planned.

If breeding in hand, good communication between personnel involved is paramount to ensuring the safety of the breeding. First, one prepares the mare in heat for natural cover by wrapping her tail to prevent laceration of the stallion's penis by the hair during breeding and washes her perineum with a mild soap, rinses it well, and dries it with a clean paper towel. One may apply a leather harness to her crest to prevent the stallion from biting her during breeding. One may apply hobbles to her rear legs to deter the mare from kicking the stallion.

Many choices of hobbles are commercially available. Desirable hobble attributes include comfort, ease of application, ease of removal (ensuring a quick release if needed), and simplicity so that the stallion cannot become entangled in the ropes or straps. Perhaps the simplest, safest, and most effective hobble design consists of a two pieces of soft cotton rope that fit many different mares (Figure 16.6-2). The first cotton loop slips loosely around the neck of the mare to rest against the point of both shoulders. The second portion is a longer cotton rope attached to a padded leather anklet designed to fit snugly around the rear pastern of the mare. One straps the anklet around the left rear pastern, brings the left rear leg well under the body of the mare, pulls the rope gently between the front legs of the mare, and ties a quick release knot just below the point of the shoulder on the left side. One may use additional restraint devices. One may apply a twitch just minutes before the 1067
stallion arrives or may sedate the mare. These additional restraints may inhibit the desired response, however, 1068
and the mare may fail to show signs of heat in response to the stallion.

Figure 16.6-2 A simple yet effective hobble.

All personnel stand on the left side of the horses, thereby allowing the horses to move unencumbered to the right if necessary. The mare handler steadies the mare as the stallion mounts and breeds her. The stallion handler is perhaps at the most risk during in-hand breeding (or semen collection) and therefore may direct the cover. Neither size nor strength is necessary in a stallion handler; rather a calm, firm, knowledgeable horse

person fares the best in the breeding shed. The quality ofthe ejaculate often reflects the expertise of the stallion handler.

After ejaculation a variable latency period occurs until the stallion begins to dismount. In field breeding the mare initiates the dismount by moving away from the stallion. Patience and ingenuity are needed duringin-hand breeding because theoretically the restrained mare cannot move. Because of a possibility that a mare may kick during the dismount, the heads of both horses are turned to left simultaneously, causing their hind ends to move to the right and thereby creating an adequate space between them. If one requires a dismount semen sample, expediency and experience are necessary to obtain it between the end of ejaculation and the dismount.

16.6.4 Artificial Insemination

Most equine breed registries, with the notable exception of the Jockey Club, not only have sanctioned but also have encouraged the use of artificial insemination. The advantages to breeding horses by artificial insemination are numerous and range from safety for the horses and their handlers to enhancing the value of the stallion by increasing the number of his offspring produced per year (Box 16.6-1). Use of frozen semen for inseminationhas additional advantages (Box 16.6-2). Althoughcryopreserved semen offers an attractive alternative for many reasons, it also can require more intensive mare management and in some cases results in lower pregnancy rates.

16.6.4.1 BOX 16.6-1 ADVANTAGES OF ARTIFICIAL INSEMINATION USING COOLED SEMEN

Allows many mares to be bred with a single ejaculate.

Prevents overuse of the stallion.

Enables mare owners to breed to any stallion regardless of distance, especially with cryopreserved semen.

Enhances and encourages genetic variability and hybrid vigor.

Controls management of the difficult breeder.

Reduces the chances of spread of infectious disease, venereal and systemic.

Reduces possibility of injury to mare and stallion.

Eliminates transportation and board expenses of the mare.

Allows evaluation of semen quality at each insemination.

Allows advance shipment of cryopreserved semen and increased availability.

May result in less variability in semen quality because of central processing station.

In an attempt to mimic the events of natural mating and yet ensure minimal contamination of the reproductive tract of the mare during artificial insemination, the following techniques have been described.[23] The mare should be restrained properly, preferably in stocks to protect the inseminator. Other devices, such as a twitch, have been used effectively for restraint but are usually unnecessary. If chemical restraint is warranted, the use 1068

of α-agonists such as xylazine (Rompun, Bayer Corp., Shawnee Mission, Kansas) may be preferable to other agents because of their effect on contractility of the uterus while it is under the influence of estrogen, particularly in mares exhibiting a delay in uterine clearance following insemination.[24] One bandages the tail of the mare and ties it away from contact with the vulva and perineum and washes the vulva well with liquid soap and rinses it thoroughly with water. One repeats the washing a minimum of three times until the area is visually free of any debris. One then should dry the vulva and perineal area with a clean paper towel. 1069

16.6.4.2

BOX 16.6-2 ADDITIONAL ADVANTAGES TO USING CRYOPRESERVED SEMEN FOR INSEMINATION

Ability to breed any stallion in the world, regardless of distance.

Ability to ship the semen well in advance of breeding so that it is available when needed.

Preservation of stallion genetics for many years.

Insurance against unavailability, injury, or death of the stallion.

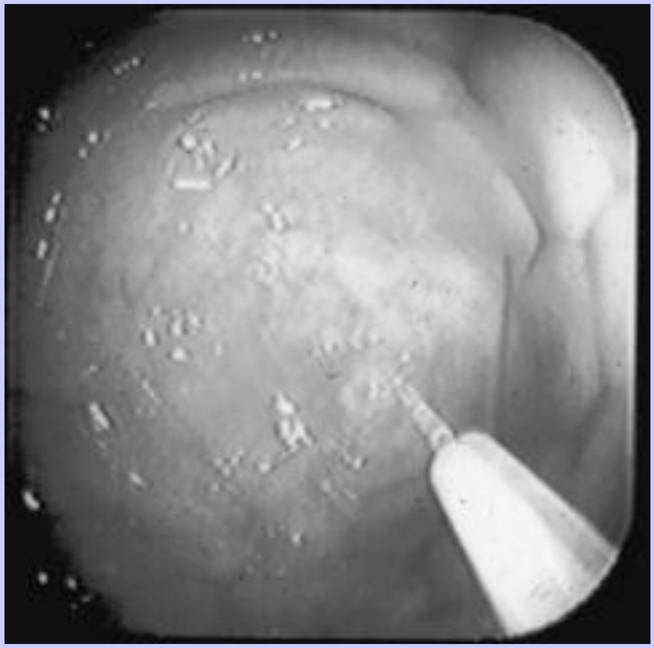
Less variability of semen quality.

If one is breeding with cooled semen, the semen does not have to be warmed after removal from the storage container. If one is breeding with frozen semen, one must thaw the semen before insemination. One must maintain stored semen at −196° C until ready for use, at which time one must follow the thawing and insemination instructions that accompany the frozen semen. Thawing protocols at high temperatures (50° to 75° C) require closer adherence to exact immersion times than do low temperatures (37° C). Depending on the cryopreservation techniques and sperm concentration per straw, a breeding dose may consist of a single straw(0.5 to 5.0 ml) or multiple straws.

The inseminator dons a sterile sleeve and grasps a sterile insemination pipette between thumb and palm to protect the tip in a sterile environment. If one is breeding with 0.5-ml straws of frozen-thawed semen, one mayuse a sterile insemination gun instead of the pipette. One applies nonspermicidal sterile lubricant sparingly to the sleeve covering the forefinger. Prepared semen should be contained in a nonspermicidal syringe and protected in the nonsterile hand from adverse environmental conditions such as ultraviolet light, cold, heat, and air.

The inseminator inserts the sleeved hand, continuing to protect the tip of the insemination pipette, through the lips of the vulva and into the vaginal vault and inserts one to two fingers through the cervical os. The finger(s) then act as a guide for advancement of the insemination pipette through the cervix approximately 1 cm into the uterus of the mare. If the advancement of the pipettehas not encountered resistance once in the uterus, one can advanced it carefully and gently into the desired (usually ipsilateral to the developing follicle) uterine horn. This advancement is not always possible because of the amount of endometrial edema and folding, and one must take extreme care to avoid damaging the endometrium. Once the pipette is satisfactorily in place, one depresses the plunger of the syringe and deposits the semen inthe uterus. If one encounters resistance on depressing the plunger, the tip of the pipette may be obstructed by the endometrium and may require repositioning. One may introduce a small amount of air to clear the pipette. Massage of the vaginal vault during withdrawal of the inseminator's hand may stimulate uterine contraction and aid in propulsion of spermatozoa to the uterotubal junction.

Figure 16.6-3 Through hysteroscopic insemination, lessthan 0.25 ml of semen is deposited on the oviductal papilla. (Courtesy E.L. Squires, Colorado State University, Fort Collins.)



The area of semen deposition has received great attention recently. Although pregnancy rates appear to be independent of volume of semen,[25] minute volumes and numbers of motile spermatozoa (as low as 1×10^6 motile sperm) deposited at the uterotubal junction (Figure 16.6-3) or within the oviduct have shown promising pregnancy results.[26–28] Furthermore, deep uterine insemination also enhances pregnancy rates.[26] Withthe procedure described by Rigby,[29] one first passes the insemination pipette transcervically into the uterine body; then directs it into the uterine horn ipsilateral to the dominant follicle; and through transrectal manipulation, moves the pipette into the horn by gently threading the uterus around the pipette. However, because ofthe degree of edema of the mare endometrium during estrus, one must exercise caution to avoid damaging the endometrium with this technique.

16.6.5 Optimizing Pregnancy Rates

Insemination of mares with a minimum insemination dose of 500×10^6 progressively motile spermatozoa every other day long has been accepted to maximize pregnancy rates.[30] Some stallions with apparently superior fertility may provide maximum pregnancy rates at much lower dosages. As with bulls, the minimal insemination dose for optimizing pregnancy rate may be male-dependent.[31] However, unlike with bulls, no evidence is currently available that increasing the insemination dose can compensate for morphologic defects in 1069
stallion sperm. Fortunately, the number of sperm in a single ejaculate from a normal stallion far exceeds this 1070
dose, provided that the stallion is not suffering from overuse. Therefore depending on the intensity of management, most breeding operations using in-hand breeding aim to cover mares shortly before ovulation or,

if the stallion is not breeding other mares, every 48 hours while the mare is in standing heat. To prevent overuse of the stallion and to enhance pregnancy rates, one should examine mares with transrectal palpations and ultrasound at least every other day and should breed them when ovulation is expected within 24 to 48 hours. Postovulation breeding, although at times successful, more often is associated with embryos of inferior quality.[10,32–34]

In a breeding program that uses artificial insemination, generally accepted fact is that the fertility of most stallion semen is greatest on the farm, followed by that of shipped cooled semen, with frozen semen being least fertile.[35] Exceptions to this rule invariably occur. Because the fertility of semen appears to be stallion-dependent, good breeding management requires an awareness of the minimal insemination dose necessary to maximize pregnancy rates for each stallion. The aim in a cooled semen insemination protocol is to provide a minimum insemination dose (500×10^6 progressively motile sperm) tobe inseminated every other day before ovulation. Jasko, Moran, Farlin, et al.[36] have reported further that the semen must be extended to 25 to 50×10^6 motile sperm per milliliter to achieve maximal pregnancy rates.

In an artificial insemination program that uses cooled shipped semen, often more than a single dose of semen is sent. Controversy exists regarding the fate of the unused doses: Should they remain in storage at 4° C, or should they be inseminated immediately into the mare? Supporters of the Equitainer (Hamilton-Thorne Research Inc., Danvers, Massachusetts) hypothesis argue that the sperm storage sites in the oviduct of the mare are filled with the first insemination and do not need to be replenished for at least 24 hours[37]; therefore using the mare as the incubator for the second dose is wasteful because the excess spermatozoa will be expelled. Those in favor of the mare as the optimal reservoir believe that although the motility of the second dose of semen fares well in the Equitainer, it does not necessarily reflect the fertility of this dose and therefore the sperm fare better in the mare.[38] The studies that have addressed this argument have used few stallions in the experimental design or have failed to take into account the interval from insemination to ovulation. In the study presented by Love, Thompson, Lowry, et al.,[39] maintaining the fertility of the sperm when cooled at 5° C may yet again be stallion dependent; stallions with poor fertility appear to have more chromatin damage with cooling than stallions with good fertility. The most convincing evidence for sequential breedings arises in a studies by Heiskanen, Huhtinen, Prihonen, et al.[40,41] These researchers found that mares bred with semen stored at 5° C for up to 40 and 80 hours have pregnancy rates of 87% and 65%, respectively, thus demonstrating acceptable pregnancy rates with stored semen. Still, the optimal means for preserving the fertility of extra doses of semen remains a controversial subject, and the answer is not entirely clear, perhaps because again the fertility may vary with individual stallions and mares.

Occasionally, a suboptimal dose of semen arrives: the semen may be extended improperly, the sperm numbers may be low, or the motility or morphology may be poor. If the total volume of semen is not so great that it is expelled through the cervix on insemination, one should make every attempt to inseminate enough semen to comprise the optimal dose for pregnancy. If the volume is too great, one may centrifuge the semen, but this may jeopardize the motility of the semen. Therefore reinseminating the mare 6 to 12 hours after the first insemination with a second dose is perhaps best in attempt to cover her with an optimal dose over 24 hours.

Pregnancy rates with transported cooled semen have been reported to range from less than 20% to greater than 80%.[42] Although somewhat dependent on the fertility of the mare and stallion, the extreme variability of the fertility rate often is due to other management factors. These factors include handling and management of the stallion, handling and management of the semen, extension of the semen, shipment of the semen, number of motile sperm inseminated, management of the mare, preparation of the mare for breeding, insemination technique, handling of the semen during insemination, and postinsemination management of the mare.

Therefore pregnancy rates reflect not only the fertility of the horses but also the expertise and conscientiousness of the personnel involved in this endeavor.

With cooled semen, insemination of mares within24 hours before ovulation is recommended to allow ample time for capacitation of the spermatozoa and transport to the oviduct. If ovulation fails to occur in the expected time frame, reinsemination every 24 to 48 hours with at least 500×10^6 progressively motile spermatozoa should optimize pregnancy rates. However, repeated inoculation of the uterus with rebreeding can cause problemsin mares that are susceptible to endometritis or a delay in uterine clearance.

Pregnancy rates with frozen-thawed semen also demonstrate a wide range of success. Cryopreserved semen from most stallions generally is accepted to have lower fertility than cooled semen, but this is not always the case. Frozen-thawed semen probably does not maintain viability within the mare for as long as fresh or fresh-cooled semen; this effect has been demonstrated in culture.[43] Ellington, Ball, Blue, et al. have suggested that 1070
the cause of this short viability may be due to the capacitation-like changes associated with frozen-thawed 1071
sperm.[7] Furthermore, fewer numbers of spermatozoaare found bound to the oviduct of the mare following insemination with frozen-thawed semen. If indeed a selective mechanism exists for sperm-binding capacity within the oviduct and that sperm must be noncapacitated, then in the process of freezing and thawing, irreversible damage may cause spermatozoa to lose this binding ability.[43] Lower pregnancy rates associated with insemination of frozen-thawed semen also could be caused at least in part by the intensive management often required for success. Although many researchers have demonstrated acceptable per cycle pregnancy rates of 25% to 45%[44–46] when breeding every 24 hours or postovulation, much higher pregnancy rates (>70% per cycle) have been achieved with intensive mare management that includes pre- and postovulation breeding.[44–49] In practice, the cost of frozen semen often precludes frequent inseminations.

The results of a recent retrospective study performedby Loomis[49] demonstrated that no significant difference existed in first-cycle pregnancy rates, seasonal pregnancy rates, or number of cycles per pregnancy between cooled and frozen semen shipped from one facility to a large number of mare owners. In this study, the inseminators were instructed to breed the mares with the frozen-thawed semen pre- and postovulation and close to ovulation. In this instance, management and selection of the stallions was optimal, and the stud farm was involved closely (through instruction and communication) with selection and insemination of the mares. Therefore management and selection of breeding stock may assume even greater importance when breeding with frozen semen.

The number of morphologically normal, progressively motile sperm that yields optimal pregnancy rates with frozen-thawed semen is likely, again, to be stallion and management dependent. In one objective study, Leipold, Graham, Squires, et al.[45] found that the optimal concentration at which to freeze spermatozoa, with respectto pregnancy rate, is equal to 800×10^6 total sperm contained in a 0.5 ml straw. However, the number of stallions was limited in this study, and per cycle pregnancy rates, although acceptable, were only 40%. Most researchers suggest that a minimum of 200×10^6 progressively motile sperm are necessary for an optimal breeding dose, and many inseminate with a higher number. Researchers that report per cycle pregnancy rates in excess of 50% aim to inseminate at least 200×10^6 motile sperm pre- and postovulation, with only a 6- to 8-hour interval between inseminations (with ovulation occurring during this interval).[47–49]

Although predicting ovulation is challenging and management of mares to be inseminated with frozen semen is time consuming, timely treatment with deslorelin acetate can ease management greatly. Not only does this drug

reliable stimulate ovulation, but also the window of ovulation is so small that far fewer examinations of the mare are necessary for success. Furthermore, its use can curtail, if not eliminate, late-night breedings.

16.6.6 Future Techniques

Procedures that were once considered to be advanced reproductive technology have become a routine part of many private practices. These procedures incude embryo transfer, gamete intrafallopian transfer, and cryopreservation of spermatozoa and oocytes, to name a few. These techniques offer the possibility of preserving valuable lines that otherwise may be lost in breeding stock. However, the increased awareness of management techniques and fertility evaluations perhaps has permitted the greatest increase in breeding efficiency found in the horse industry today.

16.7—Equine Embryo Transfer

Elizabeth Metcalf

Unlike the stallion, the mare is limited in the number of offspring that she can produce in her lifetime. Embryo transfer offers a means for enhancing production of offspring from mares of superior genetic lines or that are incapable of carrying a foal to term. More specifically, this procedure offers the following advantages:

1. Embryo transfer allows a mare to remain in competition while still producing valuable offspring.
2. Embryo transfer allows production of offspring from mares suffering from pathologic conditions of the uterus severe enough to prevent carrying a foal to term.
3. Embryo transfer allows production of offspring from mares suffering from systemic illness that prevents them from carrying a foal to term.
4. Embryo transfer allows for production of offspring from mares with musculoskeletal disease in which their health may be at risk for carrying a pregnancy to term or delivering a foal (fractured pelvis or hip or severe arthritis, for example).
5. Embryo transfer prevents risk of postfoaling complications in the valuable mare or older mare at risk.
6. Embryo transfer allows more than a single offspring to be born within a given year.
7. Immature (2-year-old) mares yet unable to carry a foal to term are capable of producing embryos that have a good survival rate in mature recipient mares.
8. In breed registries in which the value of the offspring often depends on a determined birthdate, embryo transfer allows mares that foal late in the season to produce an embryo for that year and yet also to be prepared to be bred early on the subsequent season because they have been left open.
9. The procedure has proved invaluable in many research projects comparing effects on twins that arise from embryo splitting or double ovulation.

As breed registries have permitted registration of the foals produced by embryo transfer, the technique rapidly has become a routine procedure offered in many equine private practices. Although most practices do not maintain a herd of recipient mares and most small-scale mare owners do not provide enough recipients, the procedure of flushing embryos from donor mares and shipping the embryos to recipient mares at a distant location has grown in popularity. Still, despite the numerous advantages to transferring embryos, the procedure is an expensive endeavor that may cost in veterinary and mare care alone in excess of $10,000.[1] Coupled with the stud fee, these offspring, if the procedure is successful, are indeed valuable.

16.7.1
Factors Affecting Success Rates

Three major factors affect success rates in an embryo transfer program: the fertility of the mares (donor and recipient), the fertility of the semen, and the expertise of all technical and veterinary personnel. Best management practices optimize all three factors for success. One should evaluate all horses involved by a

breeding soundness examination, the extent of which depends on the age, history, and parity of the mares and the reproductive history of the stallion.

16.7.1.1 FERTILITY OF THE DONOR MARE

The ideal candidate for a donor mare in an embryo transfer program is a 3- to 10-year-old, healthy, reproductively sound mare. Foss, Wirth, Schlitz, et al.[2] reported high embryo recovery rates from show mares (84.2%) followed by an acceptable rate from multiparous, nonbarren mares (59.7%). However, mares with a history of infertility showed a significantly lower embryo recovery rate (30.0%). Unfortunately, the value of many mares is not realized until they are older, and some offspring have exhibited superior performance. Age of the mare appears to play a major role in fertility[3]; early loss of pregnancy is a common and frustrating problem encountered in older mares. Investigation into the causes of this age-associated infertility has led researchers to examine changes that occur in the reproductive tracts of aging mares: the uterine environment, the uterine tube environment, and ovarian function.

The numbers and quality of oocytes differ greatly between young and aged mares.[4] Oocytes from older mares (i.e., >20 years) have significantly more morphologic anomalies.[5] The clinical impression of many practitioners is that delayed development occurs in embryos obtained from older mares.[4,6] In evaluation of equine embryo quality and viability, not only have young mares (<10 years old) been reported to produce more embryos, but also the embryos that are recovered from them are of significantly superior quality compared with embryos from older mares.[7–9] Embryos are graded based on morphologic characteristics and size (grade 1, excellent; grade 4, poor).[10] Transfer of grade 1 embryos results in significantly higher 50-day pregnancy rates (70% to 80%) than transfer of grade 4 embryos (30% to 40%).[9] Transferred embryos classified as grades 1 and 2 demonstrate significantly higher pregnancy rates than grade 3 embryos.[10] Embryo loss between 12 and 50 days of gestation was significantly greater with grade 2 embryos than with grade 1 embryos.[11]

Because the number of blastocysts recovered fromthe oviductal lumen 2 days following ovulation are not different based on mare age,[6,11] fertilization and early cleavage steps may not be the limiting factors in 1073
production of embryos in older mares. However, pregnancy ratesat 4 days demonstrate a significant 1074
difference based on mare age.[6,12] Although age-associated degenerative and inflammatory changes to the endometrium and its associated blood vessels of the mare are well documented and in some cases may contribute to lower foaling rates in old mares, the defect that causes early embryonic losses appears to occur before the mature blastocyst can be found within the uterus.[13] Early (2-day) pregnancy rates are not different based on age of the mare,[12] but 3-day pregnancy rates are decreased significantly in aged mares.[14] Day 4 embryos collected from the uterine tube of old mares and transferred to the uterus of young normal mares show significantly lower survival rates.[15]

Apparently, older mares require superior nutritional support, particularly during the vernal transition period to hasten the interval to ovulation.[16–19] Follicular development is prolonged in older mares, especially as they approach ovarian senescence.[20,21] The most common cause of early pregnancy loss in older mares appears tobe an intrinsic defect within the oocyte itself or in the physiologic events that occur before the formation of a day 3 embryo. Other factors, such as failure of maternal recognition of pregnancy, immune-

mediated causes, chromosomal aberrations, reaction to stress, nutrition, hormonal insufficiencies, and postovulatory insemination may play a role in early pregnancy loss or delayed embryonic development.[22]

16.7.1.2 FERTILITY OF THE RECIPIENT MARE

A young, healthy reproductively sound mare is the ideal candidate to act as an embryo recipient. Factors that further enhance success rates in the recipients include good nutrition, good general health care, minimal stress, and hormonal synchrony with the donor mare. Ideally, the recipient mare should ovulate during a time period from 1 day (+1) before to as many as 6 days after (–6) the donor mare to optimize pregnancy rates.[23,24] Carnevale, Ramirez, Squires, et al. have reported that embryo loss rates are significantly higher in recipient mares that ovulate 7 days or more (–7) after the donor mare.[11] One may encourage synchrony between the ovulations of the donor and recipient mares through the administration of prostaglandin $F_2\alpha$ alone or with progestin compounds.[25] Ovulation-induction agents such as human chorionic gonadotropin or deslorelin may further enhance desired synchrony.

To eliminate the need for synchrony, many researchers have used ovariectomized recipient mares that have been treated with progestins alone or a combination of progestins and estrogen.[26–28] Although McKinnon, Squires, Carnevale, et al.[28] found that pregnancy rates were similar between ovariectomized, progesterone-supplemented mares and synchronized recipients, results in the field have been unreliable using ovariectomized recipients, perhaps because ovariectomized mares that remain open for a season appear to be less optimal candidates for subsequent recipient seasons. From an economic standpoint, ovariectomized mares also require upward of120 days of progestin supplementation.[29] Researchers also have evaluated the suitability of hormone-treated mares in the beginning of the transitional period as embryo recipients, but pregnancy rates are often not as high as those in recipients that are cycling regularly.[11]

Uterine tone at day 5 following recipient ovulation represents a useful predictive indicator of success in transfer. Recipient mares with good uterine tone 5 days after ovulation had significantly higher pregnancy rates at day 50 than mares with poor to fair uterine tone.[11] McCue, Vanderwall, Keith, et al.[30] have shown that mares that qualify as recipients based on uterine tone have significantly higher progesterone concentrationsat day 5 than mares who failed to qualify. This findingis consistent with another study reported by Sevinga, Schukken, Hesselink, et al.[31] that found that the size of the corpus luteum and progesterone production are higher at day 8 or 9 after ovulation in pregnant versus nonpregnant mares.

Although veterinarians generally accept that the parturient mare determines the size of the foal at birth, research has demonstrated the need to avoid choosinga recipient pony mare to deliver the foal of a donor Warmblood mare.[32] Allen[33] has demonstrated that the size of the recipient mare does affect the adult size of the offspring. Wilsher and Allen[34] split equine embryos and transferred these identical twins into recipient mares of varying heights. Although the mare appeared to determine the size of the foal at birth, the adult height ofthe transferred embryo appeared to depend on the size of the recipient mare. Therefore perhaps one is wiserto consider choosing donor and recipient mares of similar size.

16.7.1.3 FERTILITY OF THE SEMEN

The quality of semen affects the success rate of embryo recovery.[35] In general, one obtains the best results when the mare is inseminated with semen collected on the farm (or is bred under natural cover), followed by

sementhat is cooled and shipped to arrive within 24 hours of collection, followed by frozen semen.[36] High pregnancy rates have been demonstrated when the mares are inseminated pre- and postovulation during a 12-hour period.[37] Results from an embryo transfer program ina private practice over a 2-year period of evaluation support this discrepancy in fertility based on the typeof semen, with fresh, chilled, and frozen semen resulting in embryo recovery rates of 55%, 44%, and 32%, respectively.[38] 1074

1075

16.7.1.4

EXPERTISE OF THE VETERINARIAN

The veterinarian's role is not only to determine the optimal time for breeding but also to recognize abnormalities as they arise. Abnormalities such as delayed uterine clearance[39] or hemorrhagic follicles can be detrimental to successful embryo recovery. The veterinarian also should be experienced in embryo recovery and transfer techniques to achieve the most successful pregnancy rates. Owners need to have realistic expectations before embarking on this expensive endeavor. They must realize that even with a young, fertile mare bred with fertile semen and under the care of an experienced veterinarian, the best embryo recovery rates are only 70% to 80%. If semen shipped cooled or frozen is used, then the success rates are often lower.[40]

16.7.2

Procedure for Embryo Recovery

Most embryo flushes are attempted on days 7 or 8, with the day that the donor ovulated designated as day 0.Day 0 is the first day that a corpus hemorrhagicum is visible on transrectal ultrasound examination, assuming that mare has been examined at least daily. If one examines a mare more frequently, as is often the case when breeding with frozen semen, one still determines day 0 by the first appearance of the corpus hemorrhagicum. Occasionally, another question of ovulation may arise because of the presence of a hemorrhagic follicle; these anomalies occur more often in transitional and older mares. In these cases, ovulation generally is believed not to have occurred.[41]

The developing embryo enters the uterus after day5 at the morula or early blastocyst stage.[42] Enormous growth of the blastocyst and rapid expansion of the inner cavity, the blastocoele, occur during the next few days. Most embryos destined for transfer are flushed as expanded blastocysts (days 7 or 8) because they appear to optimize transfer pregnancy rates.[43–45]

One lavages the uterus of the donor serially with liters of Dulbecco's phosphate buffered saline or synthetic oviductal fluid warmed to 37° C (Figure 16.7-1). One may add antimicrobial agents and 1% fetal calf serum (FCS; Hyclone Laboratories, Logan, Utah) to the lavage medium. Although many Foley-type catheters have been used for the lavage, a large-bore (8.0-mm) sterile silicone catheter (80 cm; Bivona ET flushing catheter, Western Veterinary Supply, Grapevine, Texas) with an inflatable cuff is often ideal for most donors presented in practice. The uteri of some older or multiparous mares may require more than a single liter of fluid to distend the uterus. Likewise, the smaller uteri of maiden mares may take less than 1 liter for maximum distention. Often one can determine this by the ease of fluid flow into the uterus. One evacuates the uterus by gravity flow and passes the recovered fluid through a sterile recovery cup lined with a 0.75-μm filter (Harvet, Spring Valley, Wisconsin). One must ensure that the cup does not run dry; a certain amount of fluid must remain in this cup at all times to bathe the embryo. Even though most embryos are recovered in the first flush, one must repeat this procedure 2 to 3 more times, always measuring the recovered fluid on each flush so that when the procedure is complete, most of the fluid has been recovered. One performs transrectal massage of the uterus for the last two flushes, ensuring recovery of all fluid introduced to the uterus.

Once in the laboratory, one gently swirls the contents of the cup and pours the contents into search dishesthat have been maintained at 37° C. One rinses the cupwith 20 ml of remaining Dulbecco's phosphate buffered saline solution and decants it into the search dishes. Using a stereoscopic microscope, usually at 15× magnification, one methodically seaches for the embryo. Once found, one evaluates the embryo at higher magnification for age, size, and morphology and then washes it 3 times in lavage medium with 10% FCS in preparation for shipping or transfer. Often one adds antimicrobial agents to this medium as well.

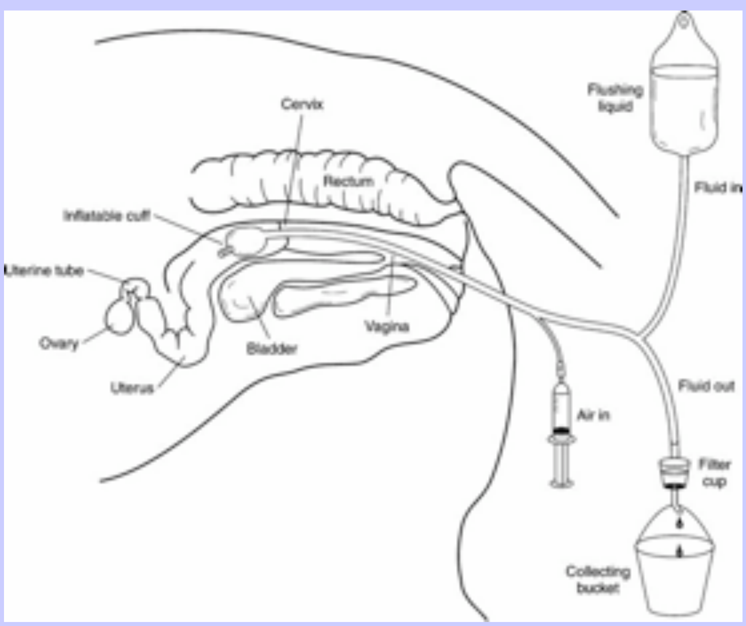
16.7.3 Embryo Transfer into theRecipient Mare

Surgical and nonsurgical techniques have been used successfully to transfer mare embryos. Surgical transfer via a standing flank laparotomy demonstrated the most favorable pregnancy rates for many years. However, this procedure is more expensive, more labor intensive, and time consuming for the veterinarian, and it poses a higher risk to the recipient mare. Over the past few years, nonsurgical transfer has been reported to achieve similar, if not superior, pregnancy rates for many clinicians.[2,40,46] This success rate appears to depend on the experience and expertise of the veterinarian performing the transfer.

One loads the embryo into a sterile 0.25-ml or 0.50-ml straw using a ureteral catheter adapter (Cook Urological, Spencer, Indiana) attached to a tuberculin syringe. The size of the straw depends on the size of the embryo. To ensure the midstraw location of the embryo at all times before transfer, one first loads the straw with lavage medium (10% FCS), then with an airpocket, then with medium (10% FCS) containing the embryo, then with another airpocket, and followed at last by medium(10% FCS). For nonsurgical transfer, the first fluid section must penetrate the wick of the straw to prevent loss of the contents of the straw by gravity. This sequence not only allows verification of the location of the embryo but also reduces the amount of fluid inoculated into the uterus of the mare on transfer. 1075

1076

Figure 16.7-1 Embryo flushing: the inflated catheter seals the cervix. (Courtesy T. Ayres, Aurora, Oregon.)



One loads the straw into a sterile insemination gun. Although several commercially available guns have been designed to fit the different sizes of straws, some veterinarians prefer to use a stainless steel reusable gun, and others prefer an intrauterine pipette for transfer of large embryos. Manipulation of the cervix or inoculationof the uterus during transfer long has been considered detrimental to a successful pregnancy. This invasion of the reproductive tract of a diestrus recipient mare also has been suspected potentially to lead to eventual regression of the corpus luteum via prostaglandin and/or oxytocin release. Thus one must take many steps to preserve the corpus luteum and thus the transferred pregnancy.

Although studies have shown that no benefit accrues from treating the recipient mare with altrenogest (Regumate, Intervet Inc., Millsboro, Delaware) or flunixin meglumine (Banamine, Schering-Plough Animal Health, Union, New Jersey), many practitioners continue to administer these drugs to mares before transfer of the embryo. Some also use a single intramuscular dose of procaine penicillin (Aquacillin, Vedco, St. Joseph, Missouri) for its antibiotic action, whereas others administer dexamethasone (Dexaject SP, Burns Veterinary Supply, Rockville Centre, New York) for its antiinflammatory effects, terbutaline (Franck's Veterinary Pharmacy, Des Moines, Iowa) for its tocolytic action on the uterus, and propantheline bromide (Franck's) for transient relaxation of the rectum.[2]

Unfortunately, little scientific data is available to validate the merits of these therapies. Sedation of the recipient mare depends on her temperament and degree of discomfort during the procedure. Based on work by LeBlanc, DeLille, Cadario, et al.,[47] tranquilization using an α-agonist such as dormosedan may cause less stimulation of uterine contraction because the uterus of the recipient mare is under the influence of progesterone from the corpus luteum. When β-adrenoceptors predominate, they inhibit contractions.

One secures the loaded sterile embryo transfer gun, perhaps shielded by a sterile outer guard sleeve, in the palm
with the thumb. One applies a small amount of sterile lubricant and inserts the hand and gun transvaginally. 1076
One digitally palpates the external cervical os and passes just the tip of the gun gently through the guard sleeve 1077
and then the remainder of the cervix. At this point, many prefer to deposit the embryo in the uterine body. Ifone is planning to deposit the embryo in the uterine horn instead, the veterinarian then inserts a well-lubricated arm into the rectum of the recipient, locates and grasps the uterine horn, and gently threads the tipof the gun into the uterine horn. One slowly depresses the plunger, releasing the embryo from the straw asthe gun is withdrawn. Because of equine embryo mobility, into which horn the embryo is deposited does not matter.

One performs surgical transfer of an embryo on a sedated recipient mare aseptically prepared for a routine flank incision. Usually one uses an inverted L or line block over the paralumbar fossa for local anesthesia. The surgeon exteriorizes the uterine horn of the mare and makes a small puncture with a cutting-edge suture needle. The surgeon then enlarges the hole slightly with iris forceps and inserts the sterile straw containing the embryo through the hole into the uterine lumen to deposit the embryo. The surgeon places the uterine horn back into the abdomen and then repairs the incision with a routine three-layer closure.

One can detect a developing embryonic vesicle by transrectal ultrasound examination as early as 5 daysafter transfer. If the embryonic vesicle is not visible at this time, one must plan to recheck the mare every 48 hours at least through day 16. Carnevale, Ramirez, Squires, et al.[11] have shown that the presence or absence of an embryonic vesicle at 5 days is an important predictorof pregnancy loss by 50 days. Recipient mares in which the embryonic vesicle is large enough to be seen on the first pregnancy examination (usually 5 days) have fewer embryonic deaths than mares in which the vesicle is not seen until subsequent examinations. Ginther, Bergfelt, Leith, et al.[48] support this theory; they also found that undersized embryonic vesicles are associated with a higher rate of pregnacy loss.

16.7.4 Shipping Embryos

Carney, Squires, Cook, et al.[49] have shown that no significant differences occur in pregnancy rates between mares that have embryos transferred immediately after collection and mares that receive cooled, transported embryos. The expense of maintaining open recipient mares is considerable, and a number of commercial recipient herds are now available to practitioners. Most of these commercial herds have limited numbers of mares, so having contracts signed and mares reserved early in the breeding season is important.

Preparing the embryo for shipping is uncomplicated. Most embryos in the United States are shipped in Ham's F-10 (Sigma Chemical Co., St. Louis, Missouri) medium buffered to an optimal pH with a mixture of 5% CO_2,5% O_2, and 90% N_2 gas.[50] The final preparation of the medium contains 10% FCS (filtered through a Millipore filter) and antimicrobial agents (usually a combinationof penicillin and streptomycin). Although most larger commercial operations send the buffered medium on ice to the practitioner the day before the embryo flush, this transport medium is simple for the practitioner to make in the clinic, providing that a tank of the appropriate gas mixture is on hand.

Several other media are available for embryo transport that eliminate the need for the gas buffer of Ham's F-10, which is necessary to maintain the correct pH for embryo transport. Moussa, Duchamp, Bruyas, et al.[51] reported that two commercially available embryo holding media (Emcare Holding Solution [ICP, Auckland, New Zealand] and ViGro [AB Technology, Pullman, Washington]) appear to have an effect on embryo viability similar to the gas-buffered Ham's F-10 for 24-hour cooled storage of embryos. However, this study did not examine pregnancy rates after transfer. Fleury, Fleury, and Landim-Alvarenga[52] recently reported that using hydroxyethyl-piperazine ethane-sulfonate (HEPES)-buffered Ham's F-10 (with 0.4% borine serum albumin [BSA]) for temporary storage of embryos gave 15-day pregnancy rates of greater than 75% in recipient mares. This medium also eliminates the need for incubation with the gases. In this experiment, embryos were stored at ambient temperature, between 15° and 24° C, thereby eliminating the need for cooling as well.

One transfers the washed embryo using a sterile0.25- or 0.5-ml straw to a 6-ml snaptop tube containing the transport medium. One tightly closes the top and places the tube in a larger tube (50-ml centrifuge tube) also filled with transport medium. One then places both tubes into an isothermalizer cup (37° C) and places that into an Equitainer (Hamilton-Thorne Research Inc., Danvers, Mass.) for shipment.

Some commercial operations with recipient herds prefer that the embryos be shipped via commercial airlines in attempt to minimize the time that the embryo spends outside of the uterus of the mare. Others believe that commercial transport companies that deliver the embryo within 24 hours are acceptable and that pregnancy rates do not differ between 12-hour and 24-hour shipment.[53] Foss[54] has shown that pregnancy rates do not differ between embryos transported by airlines versus those transported by courier services. The largest factor in choosing the means of transportation is reliability of service. Whatever means of transporting the embryo one ultimately chooses, the imperative is to ensure that the paperwork is filled out correctly and that the shipment is insured. 1077

Grant S. Frazer

16.8.1 Physiology of Gestation

16.8.1.1 MATERNAL RECOGNITION OF PREGNANCY

The zygote begins its journey down the oviduct once the oocyte has been fertilized, reaching the uterine horn by day 6.[1,2] Detailed descriptions of the early development of the equine embryo have been published and are beyond the scope of this text.[3,4] Although the term *embryo* is used routinely to describe the early conceptus, one must understand that what generally is being discussed is the embryonic vesicle and the embryo itself. These two structures ultimately develop into the fetal membranes and fetus, respectively. Embryonic development has progressed sufficiently by day 40 of gestation that the term *fetus* is used thereafter.[4]

The longitudinal arrangement of the endometrial folds may favor mobility of the spherical equine embryo.[4] After entering the tip of the uterine horn on day 6, the embryo is moved down toward the body by day 8.[5,6] The intrauterine mobility phase continues until days 15to 17, and during this period, the embryo may move between horns 10 to 20 times each day.[2,4,6,7] To maintain the pregnancy, the embryo must send a signal to the endometrium to prevent the cyclic release of the uterine luteolysin (prostaglandin $F_{2}\alpha$, or $PGF_{2}\alpha$).[8] An embryo-derived factor is the most likely cause for the suppression of $PGF_{2}\alpha$ release and interruption of the oxytocin-$PGF_{2}\alpha$ interaction in mares during early pregnancy.[9,10] The mobility of the spherical equine conceptus is critical for blockage of luteolysis,[3] and for this reason, large uterine cysts may cause pregnancy loss.[11,12] If the enlargingvesicle cannot pass by a cyst, it may be unable to contact all endometrial surfaces and thus inhibit $PGF_{2}\alpha$ production.[13] Yet another unique feature of equine reproduction is that the luteolysin is delivered to the ovary systemically.[14] Such delivery contasts with the local countercurrent uteroovarian route in domestic ruminants in which intimate contact occurs between the ovarian artery and uteroovarian vein.[15] The embryo typically becomes fixed at the base of one of the uterine horns. In postpartum mares this is usually the most involuted horn.[16–18]

16.8.1.2 PLACENTATION

The trophoblast cells of the early embryo are destinedto form the absorptive placental contact with the endometrium.[4] The mare has a unique nondeciduate, epitheliochorial, diffuse, microcotyledonary placenta.[3,19–22] The entire maternal surface of the fetal membranes becomes covered with delicate microvilli (diffuse) that interdigitate with the proliferating luminal epithelial cells to form intricately branched microcotyledons.[20,21] The interdigitation tends to be deeper at the tip of the nongravid horn, and this helps explain the higher incidence of fetal membrane retention in that horn.[23] In a normal pregnancy the noninvasive allantochorion extends slowly to fill the uterus by days 80 to 85, and its microcotyledonary architecture, which provides hemotrophic and histotrophic nutrition for the growing fetus, is not established fully until days 120 to 140.[2] During the second half of gestation, most of the mitotic activity is confined to the periphery of the microcotyledons, which are still growing.[24]

Degenerative changes (endometrosis) in the maternal endometrium can affect adversely the ability of the 1079
microcotyledonary placenta to facilitate optimal hemotrophic nutrition and exchange of waste products.[25–32] 1080
If the pregnancy is maintained, dysfunctional placental attachment can lead to the birth of small, weak foals (intrauterine growth retardation).[33,34] Likewise, the presence of twin fetal sacs deprives variable areas of each allantochorion of the necessary endometrial contact to promote development of the diffuse microvilli. Failure of development of the microcotyledons results in the characteristic white, avillous portions on the maternal surface of abortedtwin fetal membranes (see Early Pregnancy Loss and Abortion).[35,36] Although the histotrophic form of nutrition is likely to remain important throughout gestation, adequate hemotrophic nutrition is essential to support the rapid fetal growth that occurs during the latterpart of gestation.[2,22,25] The morphology of endometrial blood vessels in uterine biopsy can vary considerably depending on the age and reproductive status of the mare. In a recent study, inflammatory vascular alterations were observed in 20.5% of the endometrial specimens examined.[32] Smaller and larger arterial and venous vessels demonstrated mild to severe degenerative lesions. Unaltered vessels were detected only in maiden mares.

The incidence and severity of angiosis increases with the number of previous pregnancies and with advancing age. Changes in the endometrial vasculature of multiparous mares has been compared with the so-called pregnancy sclerosis of other species, with fraying and disruption of the membrana elastica interna, medial and adventitial elastosis and fibrosis, and calcification processes within the media. Cycles of vascular growth during pregnancy and subsequent involution post partum are thoughtto result in progressive degenerative vascular changes, as occur in multiparous mares. Aging processes, chronic inflammation, and short foaling intervals have been suggested as additional detrimental factors.[28,32] Severe angiosis frequently is combined with phlebectasia and lymphangiectasia, possibly indicating a reduced abilityof the vessels to adapt to the varying demands of uterine circulation, with a decrease of uterine perfusion and lymph drainage. Angiosis in older, multiparous mares therefore might be related intimately to infertility, possibly because of detrimental effects on early embryo nourishment and subsequent placentation.[28,32,37]

Some interesting embryo transfer experiments have demonstrated the effect that uterine capacity—and placental area—can have on the size and birth weight of the foal.[38–40] In one study, pony embryos were transferred into Draft mare recipients, and then the genetic dams were permitted to carry a full sibling to term. The final experimental outcome was three pairs of sex-matched, full-sibling pony foals. The embryo transfer foals were all larger than their siblings at birth. Although the increased milk production of the Draft mares may have explained the subsequent faster growth rates, the three foals gestated in Draft mares notably were still heavier at 4 years of age.[38] A similar embryo transfer experiment used a Thoroughbred-in-pony and pony-in-Thoroughbred comparison, with Thoroughbred-Thoroughbred and pony-pony transfers acting as controls.[40] The pony-in-Thoroughbred foals were heavier than the Thoroughbred-in-pony foals. Comparison of placental measurements (weight, volume, and surface area) confirmed the effect of nutrient supply on birth weight.[39,40] These studies confirmed earlier work in which a Shetland pony mare was inseminated with Shire semen, and a Shire mare was bred with Shetland pony semen. The foal out of the pony mare was 50% of the weight of the half-sibling that was gestated in the Shire mare. The considerable size discrepancy remained even after these half-siblings reached maturity.[41]

Equids possess the unusual ability to interbreedfreely among the phenotypically and karyotypically diverse member species of the genus to produce viable but usually infertile offspring. The mule (female horse crossed with a male donkey) is a historical example of this successful interbreeding. What is even more amazing is that mares and donkeys have been shown to be capable of carrying to term a range of true, xenogeneic extraspecies pregnancies created by embryo transfer. In these instances all of the allantochorion tissue is composed of foreign protein (see the following discussion of endometrial cups). Successful pregnancies include Przewalski's horse (*Equus prezwalskii;* $2n = 66$) and Grant's zebra (*E. burchelli;* $2n = 44$) crossed with the horse (*E. caballus;* $2n = 64$).[42]

16.8.1.3 ENDOCRINOLOGY

By day 35 a specialized, circumferential group of trophoblast cells (chorionic girdle) detach from the embryonic vesicle, and some cells successfully invade the endometrium,[2,3,43–47] where they give rise to discrete aggregates of endocrinologically active tissue (endometrial cups).[2,43,44,48] These endometrial cups become visible by day 38 to 40 as a ring of small, pale plaques that surround the developing conceptus.[3,4] Because the maternal and fetal cells (sire contribution) have differing genotypes, the fetal antigens invoke a cell-mediated immune response.[4,49,50] The influx of lymphocytes creates a pronounced, localized

immunologic reaction, and by day 120 of gestation the endometrial cups are sloughed.[49–52] The necrotic tissue and inspissated secretions form invaginations into the chorioallantois (allantoic pouches).[53] These structures are visible on the allantoic surface of the fetal membranes after the mare has foaled.

The endometrial cups produce equine chorionic gonadotropin, formerly known as pregnant mare serum gonadotropin. Equine chorionic gonadotropin (eCG) is a large-molecular-weight glycoprotein that has
activity like follicle-stimulating hormone and luteinizing hormone.[54] Periodic surges (10 to 12 days apart) of 1080
pituitary follicle-stimulating hormone release drive a series of follicular waves on the equine ovary during 1081
early pregnancy.[2,55] The eCG promotes luteinization (and sometimes ovulation) of the dominant follicle in each wave.[3,56–58] These accessory (secondary) corpora lutea augment the progesterone production from the original structure that developed at the time of conception. This process is critical to ensure pregnancy maintenance before the development of steroid production by the placenta.[2,3,59–62] The fully developed equine placenta produces significant quantities of progestins.[2,3] One can maintain pregnancy in ovariectomized embryo transfer recipient mares, providedthat they receive an exogenous progestin supplement during the early period when progesterone from corpora lutea is critical.[63] The necessity for progesterone therapy after day 100 of gestation is controversial and is discussed later in this section.[2,64,65] One may detect high levels of eCG in the blood of pregnant mares from 40 to 120 days of gestation.[2] This forms the basis of the mare immunologic pregnancy (MIP) pregnancy test. A positive MIPtest can occur when a mare is no longer pregnant, because pregnancy loss following days 35 to 40 doesnot eliminate the endometrial cups.[3] The endometrial cups can produce high levels of eCG in a mare that has suffered fetal loss during the second or third months of gestation.[66] This production results in erratic estrous behavior, unreliable follicular development, and unpredictable ovulation.

Another unique feature of early gestation in the mare is an elevation in plasma conjugated estrogen levels associated with gonadotropin stimulation of the luteal tissue.[3,57,67,68] A second, prolonged rise in estrogen levels begins by day 70, peaking around day 240, and then gradually declining toward basal levels at term.[62,69] Peak estrogen levels range between 300 and 400 ng/ml.[62] These large quantities of estrogens are secreted by the fetoplacental unit after synthesis from precursors produced by the enlarged fetal gonads.[2,61,70–73] Bilateral fetal gonadectomy between days 197 and 253 of gestation causes a precipitous drop in plasma estrogen levels that then remains basal until small foals are delivered spontaneously in 70 to 97 days.[62] After day 220 the enlarged gonads gradually shrink into an insignificant size by birth.[74] Serum estrogens in the pregnant mare include estradiol, estrone, and the equine-specific steroid ring-B unsaturated estrogens equilin and equilenin.[75,76] Estrogen assays have been used by researchers to confirm pregnancy and fetal viability.[77–79]

Four separate components combine to produce the progesterone and biologically active 5α–reduced pregnanes needed to maintain pregnancy in the mare. The primary corpus luteum is prolonged beyond its cycliclife span by the downregulation of endometrial oxytocin receptors to prevent activation of the luteolytic pathway. The waning progesterone production of the corpus luteum is supplemented from day 40 of gestation by the formation of a series of accessory corpora lutea that developin the maternal ovaries as a result of the gonadotrophic actions of pituitary follicle-stimulating hormoneand eCG.[80] The equine fetoplacental unit produces significant quantities of progesterone and C-21 progestagens.[2,59–62,81–83] The placenta (chorioallantois and endometrium) initially metabolizes maternally derived cholesterol into pregnenolone and then into progesterone. A significant amount of progesterone originates from this source,

starting from approximately day 70 of gestation.[59–62,83] In normal pregnant mares the circulating progesterone concentration starts to decline by 4 months of gestation, reaching baseline levels by day 180.[84] Thus plasma progesterone-specific assays may be of limited clinical value after midgestation.[85,86] The circulating progesterone concentration no longer indicates what is happening at the uterine level where the allantochorion secretes progesterone and progestagens directly to the endometrium and underlying myometrium. In the second half of gestation, most of the placental-derived progesterone is metabolized further into 5α–reduced pregnanes (5α-dihydroprogesterone and 20α-dihydroxy-5-pregnan-3-one, together with other 5α-reduced metabolites of progesterone and pregnenolone).[87,88] In the later part of gestation, another steroid, perhaps5α-pregnane-3,20-dione and not progesterone, has been suggested to be the important steroid precursor for the other progestin metabolites found in circulating plasma.[89] A precise biologic explanation for this mechanism has not been elucidated to date.

In the last month of gestation, the enlarging fetal adrenal gland secretes appreciable quantities of pregnenolone, which then is used by the placenta to synthesize progestagens.[2,80,87,90–93] Even at this late stage in equine gestation, adrenal 17α-hydroxylase activity is insufficient to convert the pregnenolone into fetal cortisol, and thus it passes out in the umbilical vessels and is converted to 5α-reduced pregnanes in the placenta.[2,34,87,92–94] Thus unlike the trend in ruminants, a significant increase in the plasma progestagen concentrations in the mare occurs during the last 4 to 6 weeks of gestation, followed by a precipitous drop in levels at the time of parturition.[62,81,87,95,96] A premature rise in progestins has been observed in mares with placentitis, and this phenomenon is thought to be associated with fetal stress and premature maturation of the pituitary adrenocortical axis.[40,91,97] When pony mares were subjected to intrafetal injections of adrenocorticotropic hormone (ACTH) at day 300 of gestation, maternal plasma progestagen concentrations increased significantly.[98]

1081

1082

Physiology of parturition in the mare does notfollow the well-documented ruminant model.[99–101] The precise mechanism that couples the fetal hypothalamic-pituitary-adrenal axis in the term foal is not known at this time but invariably is triggered when the fetus becomes fully mature.[102] In the mare the fetal cortisol level remains basal until the last couple of days of gestation, when a significant increase culminates in parturition.[34,103] Enhanced adrenocortical activity in the fetus is related to the onset of parturition in many species.[98] Final maturation of the fetus results in increased ACTH release from the pituitary and subsequent stimulation of the fetal adrenal cortex.[87,90,91] Not until the maturing adrenal gland attains 17α-hydroxylase capacity are the high levels of pregnenolone metabolized into fetal cortisol.[93] Disruption of these fetal maturational processes appears to play an integral part in the pathophysiology of fescue toxicosis.[94] The normal fetal maturational change (pregnenolone conversion into fetal cortisol) causes the maternal progestagen levels to plummet, resulting in a rising estrogen-to-progestagen ratio, and in the final hours, estrogen ultimately becomes dominant in the preparturient mare.[62] Studies with intrafetal injections of ACTH have indicated that precocious maturation of the equine fetus and a significant reduction in gestational length is likely to be mediated via adrenal regulation of fetal maturation and production of maternal progestagens.[98] Follow-up work by Ousey JC, Rossdale PD, Palmer L, et al.[104] demonstrated that ACTH administration (high doses) in the mare appears to accelerate fetal maturation and delivery in pony mares. Further work is required to establish the optimal gestational age and dosage for ACTH administration to mares before clinical recommendations can be given for this therapy.

Current knowledge about relaxin activity in the pregnant mare is limited.[105] Relaxin levels may serve to keepthe uterus quiescent until parturition is imminent.[105–108] Relaxin is thought to be involved in softening the pelvic ligaments to facilitate fetal passage. Mares may develop a relaxed croup just before foaling. The myometrium becomes more responsive to oxytocin and prostaglandin, and eventually the high concentrations of oxytocin and prostaglandins may overcome the inhibitory effects of relaxin.[*] The sudden dominance of estrogen is thought to promote cervical production of PGE_2. The contracting myometrium forces the chorioallantoic sac against the softening cervix and stage I of parturition ensues. The expulsive efforts during vaginal passage of the foal are driven by rising oxytocin and prostaglandin levels.[115–117] Oxytocin levels reach peak concentrations during the expulsive (stage II) phase of parturition.[106,118,119] Maternal straining (contraction of the abdominal muscles) is almost always associated with large sustained uterine contractions.

In the last week before foaling the prolactin concentration increases, and this hormone drives mammary development and the initiation of lactation.[120,121] Prolactin release from lactotrophs in the anterior pituitary is regulated by hypothalamic secretion of prolactin-releasing factor. The prolactin-inhibiting factor is thought to be dopamine.[122–125] The supraoptic and paraventricular nuclei of the hypothalamus synthesize oxytocin. The alveoli produce milk, which is expelled into the lactiferous ducts and teat cisterns when oxytocin causes contraction of the myoepithelial cells. Although nursing by the foal is assumed to stimulate the release of oxytocin from the neurohypophysis, recent research has revealed that the process is more complicated in the mare. A significant effect of suckling on oxytocin release by the mare was detected in only two of nine mares, when oxytocin concentrations were evaluated 0 to 3 minutes after suckling. When foals were prevented from sucking for 1 hour by being muzzled (n = 2) or separated from the mare (n = 2), no significant association was apparent between resumption of suckling and oxytocin release by the mare.[118]

* References 90, 96, 100, 106, 107, 109–114.

16.8.1.4

MYOMETRIAL ACTIVITY

The myometrium of the uterus is composed of an inner circular and an outer longitudinal smooth muscle layer. This arrangement of muscle fibers permits regulation of luminal size (circular) and uterine length (longitudinal).[3] The uterus is palpably flaccid during and immediately after estrus and then increases in tone and becomes turgid if the mare is pregnant.[126,127] Myometrial activity is vitally important in the uterine clearance mechanism after breeding.[128,129] Uterine contractions also play an integral role during the embryo mobility phase.[126,130–133] Between at least day 9 and day 16 after ovulation the spherical equine conceptus migrates continuously throughout the uterine lumen, propelled by peristaltic myometrial contractions.[3,134] This unusually long period of intrauterine movement ensures that the conceptus delivers its antiluteolytic signal to the entire endometrium. Conceptus mobility is high between day 10 and day 14 after ovulation but can be reduced immediately and significantly by an intravenous injection of flunixin meglumine. This suggests that prostaglandins are the primary stimulus for the myometrial contractions that drive migration of the conceptus.[134] The embryo itself produces a myometrial stimulant, and the subsequent uterine contractions result in embryo mobility.[5,130] The conceptus produces estrogens by day 12, and these, along with embryonic production of PGE_2, are thought to play a role in stimulating uterine contractions and increasing uterine tone during the mobility phase.[135–140] Progesterone is vital for embryonic development, and it plays a role in the mobility, fixation, orientation, and maintenance of the equine conceptus.[141] 1082

Administration of a progestagen (altrenogest) prevents prostaglandin-induced abortion in the first trimester of pregnancy.[142] Considerable controversy and confusion surround the use of progestagen supplementation in the later trimesters. The cellular mechanisms involvedin myometrial contractility have not been well characterized in the pregnant mare, and extrapolation from studies in nonpregnant mares may not be appropriate.[9,10,143–145] The classic theory in many species is that myometrial excitation and uterine contractility are suppressed by the progesterone block.[146] The assumption has been that progesterone and progestagens are necessary for myometrial quiescence in the pregnant mare, and the binding of 5α-dihydroprogesterone to endometrial progesterone receptors is thought to control uterine prostaglandin production and inhibit myometrial activity.[34,83,90] The oxytocin-neurophysin I gene is transcribed into messenger RNA in the endometrium of mares, and mRNA levels negatively correlate with serum progesterone concentrations.[147] However, progestagens were ineffective at controlling myometrial contractilityin vitro and did not inhibit the effects of oxytocin.[148,149] A pregnancy-induced inhibition of $PGF_2\alpha$ release is not associated with suppression of oxytocin release or oxytocin receptor density, and an embryo-derived factor is thought to be the most likely cause for the suppression of $PGF_2\alpha$ release and interruption of the oxytocin-$PGF_2\alpha$ interaction in mares during early pregnancy.[9,10] An oncofetal protein has been shown to reduce oxytocin-induced myometrial contractions in vitro, and this protein has been suggested to play a role in controlling myometrial quiescence in mares as well.[148] A reduction in circulating progestagen levels by experimental blockade with the 3β-hydroxysteroid dehydrogenase inhibitor (epostane) did not increase myometrial activity (labor) in late gestation pony mares.[82] However, despite a paucity of evidence that a deficiency of fetoplacental progestagen production is a cause of pregnancy loss in the mare, exogenous progestagen therapy is used widely as a form of preventative insurance in the belief that it promotes uterine quiescence and guards against the possibility of pregnancy failure.

Electromyographic activity in the uterus of pregnant mares increases during the last week before foaling, even though the circulating progestagen levels are still high.[96,97,106,150] One proposal is that the high levels of relaxin in the preparturient mare may act by inhibiting myometrial contractions until rising oxytocin and prostaglandin concentrations become overwhelming.[106] The number of oxytocin receptors and myometrial gap junctions may not increase in the mare until just before parturition.[106,148] A rapid membrane depolarization results in the onset of strong, coordinated uterine contractions that characterize the first stage of labor. In the last 6 hours before rupture of the chorioallantois, a significant increase in $PGF_2\alpha$ concentrations occurs before a significant increase in oxytocin concentration.[118] Oxytocin levels reach peak concentrations during the expulsive (stage II) phase of parturition.[106,118,119]

16.8.1.5 TERATOGENESIS

Little is known about embryotoxic and possible teratogenic effects of chemicals, drugs, and other agents that may be administered to pregnant mares. Phenothiazines and thiabendazole and organophosphate anthelmintics have been reported to cause pregnancy loss.[151] Likewise, ingested Sudan grass and sorghum have been reported to be toxic to the fetus.[151,152] In recent years, more definitive documentation has become available concerning the toxic effects of some medications. When griseofulvin was used to treat dermatomycosis in a mare during the second month of pregnancy, the mare carried a male foal to331 days gestation. The foal showed bilateral microphthalmia, severe brachygnathia superior, and palatocheiloschisis. The lesions were incompatible with life and the animal was euthanized. Griseofulvin administration during

pregnancy has been associated with similar lesions in other species. Because the development of the eyes and facial bones in the horse occurs in the second month of pregnancy, the lesions described in this case most likely can be attributed to griseofulvin administration.[153] Three weak, recumbent neonatal foals with skin lesions, including a thin wooly coat, were born to mares being treated for equine protozoal myeloencephalitis. The foals were anemic, leukopenic, azotemic, hyponatremic, and hyperkalemic. The pregnant mares had received sulfadiazine or sulfamethoxazole-trimethoprim, pyrimethamine, folic acid, and vitamin E orally. Serum folate concentrations in the three foals and two mares were lower than those reported in the literature for clinically normal broodmares. At necropsy each foal had lobulated kidneys with thin cortices and pale medullae. The spleen and thymus were small. Histologic examination revealed significant epidermal necrosis without inflammatory cells, thin renal cortices, renal tubular nephrosis, lymphoid aplasia, and bone marrow aplasia and hypoplasia. These observations indicated that oral administrationof 2,4-diaminopyrimidines (pyrimethamine with or without trimethoprim), sulfonamides, and folic acid to mares during pregnancy is related to congenital defects in newborn foals.[154] Further investigations are warranted to ascertain the toxic agent and to determine at what stage of gestation the fetus is most vulnerable.

16.8.2 Pregnancy Diagnosis

Standard transrectal imaging technique permits an experienced practitioner (using a 5-MHz ultrasound 1083
transducer under optimal lighting conditions) to detect up to 98% of embryos as early day 11 after confirmation 1084
of ovulation.[155] The black (anechoic) spherical vesicle is characteristic of early equine pregnancy. Novices should realize that bright white (echoic) spots on the upper and lower surfaces of the black sphere are specular reflections generated by the ultrasound waves.[156] Beginners also must appreciate that the equine embryo literally can be anywhere in the uterine lumen before fixation on day 16. One easily can make diagnostic errors unless one meticulously searches the entire length of both horns and the uterine body down to the cervix during an ultrasonographic examination. Confirmation of mobility obviously is useful in differentiating a vesicle from a cyst. At the time of fixation at the base of a uterine horn the yolk sac has three germ layers (ectoderm, mesoderm, endoderm) near the embryonic pole, and only two layers (ectoderm and endoderm) at the opposite pole. The difference in rigidity between the three-layered ventral wall and the two-layered dorsal wall explains the characteristicguitar-pick shaped image on ultrasound by day 18.[3,4] The thickest portion of the yolk sac wall (embryonic pole) rotates to a ventral position. The change from the previous spherical shape is caused by uterine turgidity and thickening of the dorsal uterine wall.[144] The increased uterine tone is responsible for the failure of the diameter of the embryonic vesicle to enlarge between days 18 and 26, thus creating the classic growth profile that plateaus during this period.[4,155]

By day 21 the amniotic cavity has formed completely and the embryo itself often is detectable by ultrasound. By day 24 one can see the allantoic sac raising the embryo off the ventral floor. The embryo itself is suspended on a thin echoic line that delineates the apposition of allantois and yolk sac.[4,155,157] This separating membrane tends to be horizontal and thus is a useful means for differentiating a singleton from twin embryonic vesicles. In the latter case the adjacent walls of the two vesicles tend to form a vertical separation. One can detect the primitive heart beat between 22 and 25 days, and it is a useful indicator of embryonic viability. By day 40 the embryo (now fetus) has been elevated to the dorsal pole because the allantois almost has displaced the vestigial yolk sac completely. The membranes and blood vessels that separate the allantois and yolk sac give rise to the umbilical cord. The increasing size of the fetus causes the fetus and amniotic sac to descend gradually back to the floor of the chorioallantoic vesicle by day 48. The remnant of the yolk sac is incorporated into the umbilical cord. The site where the umbilical cord attaches to the chorioallantois identifies the horn and site where embryo

fixation originally occurred. The dorsal attachment ensures that the developing fetus does not compress this vital area.[4]

Although ultrasonographic examinations have become standard practice for confirmation of pregnancy in mares, it is still essential that the veterinarian be competent at manual diagnosis. By 18 days after breeding, an experienced clinician may be able to perceive changes in uterine tone and consistency in the mare that, coupled with palpation of a narrow, elongated cervix, are consistent with early pregnancy. However, one should remember that not uncommonly a persistent corpus luteum provides a prolonged progesterone environment in a nonpregnant mare. One must not mistake the curvature at the base of the uterine horn for an embryonic vesicle.[3,127,158] An ultrasound image of the embryonic vesicle is required to confirm pregnancy definitively at this early stage. However, the gradually enlarging embryonic vesicle eventually creates a discernible ventral bulge that has been described as being the size of a hen's egg (day 30), goose's egg (day 35), and orange (days 40to 45).[158,159] Because dorsal distention at this stage of pregnancy is minimal, examination of the ventral aspect of each uterine horn is essential. One can make errors if the fingers are not passed far enough around the cranial aspect of the uterine horn so as to reach well under the uterine body and horns.[158] One can identify a ventral bulge consistent with a 35- to 45-day pregnancy by the distinct margins that are palpable when one moves the fingers along the ventral aspect of the uterus. The conceptus becomes more oval as it expands during the third month of pregnancy. At 90 days the chorionic vesicle has been said to be the size and shape of a football.[158,159] The age of the mare and the number of previous foals affectsthe rate of descent of the gravid uterus over the pelvic brim.[159,160] Positive pregnancy diagnosis becomes progressively more difficult as the large, heavy uterus descends into the abdominal cavity. In a normal pregnancy the uterine wall should be thin and pliable, whereas pyometra causes a thickened uterine wall that contains viscous purulent fluid. The fetus itself is not always palpable before 120 days of gestation, but after that time gentle ballottement usually allows detection of the fetus.[158,159] With palpation of some part of the fetus, one should be able to confirm pregnancy status between 5 months and term.

Blood tests for pregnancy sometimes are indicated, especially in Miniature breeds.[78] Measurement of equine chorionic gonadotropin levels verifies that the mare has endometrial cups but does not guarantee that a viable fetus is still present.[3] With this caveat in mind, eCG is suitable for determining pregnancy status in Miniature 1084
mares between 40 and 100 days after mating.[161] However, mares returning a diagnosis of pregnant should 1085
undergo a blood estrone sulfate test 100 or more days after mating to eliminate the possibility of a false-positive diagnosis. The fetoplacental unit secretes large quantities of estrogen.[69,78] Measuring blood estrone sulfate levels is recommended as the method of choice for determining pregnancy status in Miniature mares 100 or more days after mating.[162] Fecal estrone sulfate measurements provide a noninvasive alternative to blood testing from 150 days after mating. However, the discrimination between pregnant and nonpregnant levels of estrone sulfate is not as great in feces as it is in blood.[161] An early pregnant factor test recently has been reported to be useful for pregnancy confirmation in the mare. Early pregnancy factor is an immunosuppressive protein detected by a rosette inhibition test in the early pregnancy serum. Early pregnancy factor appears in the maternal blood circulation at 24 to 72 hours after mating and is detectable until the second trimester; after that, early pregnancy factor disappears from the maternal serum.[163]

16.8.3 Management of Twins

16.8.3.1 MONITORING FOLLICULAR DEVELOPMENTAND OVULATION

Most twin pregnancies arise from double ovulations.[164–166] A higher incidence of twin ovulations occurs in some breeds (e.g., Thoroughbreds and Warmbloods), andmares that tend to double ovulate can be expected to do this frequently.[3,165,167–171] Double ovulations may occur on the same day but may occur several days apart.[3,172] If a fertile stallion was used to breed the mare on the first ovulation, the viable sperm possibly still are present in the reproductive tract when the second oocyte arrives. One must remember this possibility when scanning mares for pregnancy at 14 to 16 days. At that time, scanning of the ovaries for evidence of luteal tissue from a second ovulation is good practice.

In the past, veterinarians often elected to avoid breeding a mare when two large (>30 mm follicles were palpated or to recheck the second follicle 10 to 12 hours after the first detected ovulation.[173] Because an ovulated oocyte is less likely to be viable after this time, one could perform a delayed breeding in anticipation of the second ovulation. Today the preferred strategy is to breed all eligible mares, irrespective of the number of preovulatory follicles. The widespread adoption of early ultrasonographic pregnancy examinations has permitted the focus to be placed on embryonic vesicle reduction after confirmation of a twin pregnancy.[66]

16.8.3.2 MANUAL REDUCTION

The increasing size of the embryonic vesicle, coupled with the increasing tone of the early pregnant uterus, tends to fix the conceptus at the base of one uterine horn by day 16.[3] A thorough ultrasound scan of the uterus is essential, along with a complete examination of the length of both horns plus the uterine body as far back as the cervix. Such thoroughness is especially important before day 16 because the vesicle moves freely within the lumen of both horns and the uterine body.[172] If twin vesicles are detectable, manual separation of them before day 16 is easier. Successful elimination of one vesicle is more likely at that time because the uterine walls are thin and minimal pressure is required to crush a vesicle. One often can feel a definite pop when the vesicle ruptures, but one always should confirm success by ultrasound. This sensation is attributable to the rupture of the embryonic capsule.[174]

The downside to this approach is that one easily can confuse an early embryonic with an endometrial cyst. The embryo itself does not become readily identifiable until the fourth week of pregnancy. Thus for one to note the size and location of any cysts at the time the mare is being examined for breeding is good practice. If no record of cyst size and location exists, then differentiation between early twin vesicles, versus a singleton anda cyst, with a single examination is virtually impossible. This difficulty is especially true because asynchronous ovulations are likely to result in considerable size discrepancy between the two vesicle.[3] Under these circumstances, measurement of each suspect vesicle and notation of its location may be best. A second scan in 1 to 2 days should note a size increase in any normally growing vesicle (approximately 4 mm per day).[155] Unfortunately, this delay may make separation of unilaterally fixed vesicles more difficult because of their ongoing growth and the increased uterine tone.

Manual reduction of bilaterally fixed vesicles requires less manipulation than with unilateral twins. Manual reduction is an easy procedure, and success rates exceeding 90% are not uncommon if the vesicle is crushed before day 16.[175,176] If the vesicles are fixed unilaterally, then the clinician should attempt to move the more proximal vesicle toward the tip of the uterine horn. At this location the manual reduction procedure is less likely to disrupt the remaining vesicle. One can crush the vesicle by pinching it between the thumb and fingers. Alternately, one can squeeze the vesicle against the pelvis of the mare until it ruptures. If one can separate the twins before crushing, then the success rate may be similar to that for reduction of bilateral twins.[177] If one cannot separate the unilateral twins or more than 20 days of gestation have passed, then the success rate is lower.[66] The extra pressure used to eliminate a twin vesicle after fixation is the reason many clinicians use antiinflammatory medications and progestin therapy. The likelihood of success improves with experience.[176] If one does not detect the unilateral vesicles until after day 20, then manipulations easily can result in the disruption of both vesicles. The best option in these cases may be to wait and see if natural reduction occurs.

16.8.3.3

NATURAL REDUCTION

Almost three quarters (70%) of twin embryonic vesicles become fixed unilaterally, with only 30% of twin 1085
vesicles becoming fixed bilaterally.[178,179] When twin vesicles are dissimilar in size, the incidence of 1086
unilateral fixation appears to be higher. The larger vesicle is thought to serve as an impediment to the continued mobility of the smaller vesicle.[4] Fortunately, natural reduction to a singleton is far more likely with unilaterally fixed vesicles. More than 80% of unilaterally fixed twins are likely to reduce naturally to a singleton, with more than half of these occurring between days 16 and 20.[3,178,179] However, most bilaterally fixed vesicles continue to develop.

16.8.3.4

PREGNANCY TERMINATIONWITH PROSTAGLANDIN

If natural reduction does not occur, one may consider terminating the pregnancy with a prostaglandin injection. The prostaglandin should lyse the corpora lutea that resulted from the double ovulation, and the precipitous decline in progesterone will bring the mare back into estrus. However, treatment failures have been reported.[180] Certainly, one must give this treatment before day 35. After the endometrial cups begin to form, repeated prostaglandin injections may be necessary to terminate the pregnancy. The mare more than likely will not return to normal ovulatory cycles until the cups are sloughed. In the interim they secrete eCG, a hormone that causes the development of accessory corpora lutea and augments the progesterone level in support of the early pregnancy.[3] The result is erratic estrous behavior, unreliable follicular development, and unpredictable ovulation.

16.8.3.5

TRANSVAGINAL ULTRASOUND-GUIDED ALLANTOCENTESIS

Even though the advent of transrectal ultrasonography has improved greatly the ability of veterinarians to make an early diagnosis of twin pregnancies, diagnostic errors still occur.[181,182] Such errors could be due to an early pregnancy diagnosis when the second vesicle was too small to detect, incomplete examination of the entire uterus, poor image quality, or an inability of the clinician to differentiate two embryonic vesicles that are closely apposed to each other.[182] If natural reduction does not occur or the diagnosis of twins is not confirmed until after 30 days, then transvaginal aspiration of one vesicle is an option. The results are best if

one performs the procedure before day 35.[66] Although spontaneous reduction of twin pregnancies can occur even after day 40, the probability of this occurring is low.[36,183] Natural twin reduction is more likely to occur if an obvious size discrepancy is present between the two vesicles at this time.[178,184]

If one is to attempt a transvaginal reduction, one should treat the mare with flunixin meglumine. Many clinicians also administer altrenogest orally. Because sedation causes significant uterine relaxation, most clinicians use a lidocaine enema to reduce straining.[185] The transvaginal aspiration technique uses a 5.0- or 7.5-MHz endovaginal curvilinear transducer. One should cold-disinfect and sterilize the transducer and casing before use. One then places the assembled unit in a sterile transducer cover that has been filled with sterile lubricating gel and advances the transducer aseptically until it is seated lateral to the cervix. The clinician then grasps the pregnancy per rectum and advances a sterile 60-cm, 18-gauge spinal needle with an echogenic tip along the needle guide in the transducer casing. One can use a dotted line on the ultrasound screen to select a path for the needle entryinto the embryonic vesicle. A sharp jab of the needle penetrates the vaginal wall, peritoneal lining, uterus, and ultimately the allantoic or yolk sac. With a 60-ml syringe attached to the needle, one aspirates the embryonic fluid. One should stop aspiration when a danger existsof damaging the adjacent vesicle of unilateral twins. If one is eliminating a bilateral twin, then one can move the needle within the vesicle until all detectable fluid has been aspirated.[66] The success rate is better for bilateral twin reductions.[185] Death of the remaining twin ismost likely to occur within 2 weeks of the procedure. Although reports are scarce, preliminary data suggest that experienced operators may achieve a live singleton birth in about one third of cases.

16.8.3.6 TRANSABDOMINAL ULTRASOUND-GUIDED FETAL CARDIAC PUNCTURE

In advanced twin pregnancies, one can attempt reduction by a transabdominal approach.[66,177,186,187] Fetal intracardiac injection of potassium chloride is effective but requires accurate placement of the potassium chloride into the fetal heart. One obtains the best results when the pregnancy is between 115 and 130 days.[188] At this stage experienced operators can achieve a 50% success rate. Penicillin G procaine can cause fetal death when injected into the fetal thorax or abdomen, but the effect is not instantaneous. The advantage of the latter treatmentis that it does not require precise placement of the injection into the fetal heart.[177] One should start mares on orally administered altrenogest, systemic antibiotics, and flunixin meglumine on the day of the procedure and should continue the antibiotic coverage and antiinflammatory medication for 3 days.[66]

One can use a 3.0-MHz transducer to image the90- to 130-day-old fetus in the caudal abdomen, just cranial to the udder.[182] Once the mare has been sedated, the uterus relaxes and the location of the fetuses shifts cranially. A sedative/analgesic combination that works well for this procedure is acepromazine (10 mg), xylazine (100 mg), and butorphanol (10 mg). One selects the smallest or most easily accessible fetus for reduction. One should prepare the ventral abdomen for surgery and infiltrate local anesthetic at the puncture 1086
site. One can use an 18-gauge, 8-inch spinal needle with stylet for most fetal injections.[182] The distance from 1087
the skin surface to the fetus determines the length of the needle that is required. Specialized needles with echogenic tips are available to provide better visualization via ultrasound.[177] Once one confirms the location of the thorax of the selected twin, one introduces the needle through the prepared skin, abdominal wall, and uterus. If one is to inject penicillin G procaine, then the needle may puncture the fetal thorax or abdomen. One typically injects up to 20 ml into the fetus.[177,182] One should confirm fetal death the following day.

Although the benefits of supplemental progestin therapy are debatable, many clinicians suggest that the mare be medicated for at least 2 weeks if the initial twin reduction has been successful.[182] Regular checking of fetal viability is essential because supplemental progestin therapy may prevent elimination of the dead fetuses if both die.[189] Most abortions occur within 1 to 2 months after the reduction procedure.[66] If the operator is experienced in the technique, one can expect between 40% and 60% of mares to deliver a viable singleton foal.[177,182] The eliminated twin in these cases appears as a mummified remnant contained within an invaginated pouch that protrudes into the allantoic space of the fetal membranes of the viable foal.[187] One theory for the loss of both twins following an intrafetal injection has to do with the presence of vascular anastomoses between the two fetoplacental units.[190] Circulation of the injected solution or other tissue degradation products has been suggested possibly to result in the death of the adjoining twin fetus.[182]

16.8.4 Early Pregnancy Loss and Abortion

16.8.4.1 EMBRYONIC LOSS

Once conception has occurred, any pregnancy failure up to day 40 of gestation is defined as being early embryonic loss.[3] Between 10% and 15% of mares undergo embryonic loss or abortion at some time in gestation, and most of these losses occur during the first 40 days of gestation when the primary corpus luteum is the sole source of progesterone. Yet all the available evidence suggests that untoward luteolysis is not common in this period, and the losses that do occur have other underlying causes.[80] Fertilization failure rates and embryonic losses are higher in aged mares.[191–195] Differentiation between fertilization failure and embryonic loss before day 10 is not easy because this is the earliest stage of development in which ultrasonographic detection is possible under ideal research conditions. Fertilization rates in young, well-managed mares may exceed 90% and appear to be better than80% in aged mares.[194,196] Oocytes from aged mares may be more likely to result in nonviable embryos because of inherent morphologic defects.[194,197] Carnevale transferred oocytes from young and aged mares into young recipients; thus fertilization and early embryonic development occurred in an optimal oviductal environment. The day 12 pregnancy rate in the recipients that received the oocytes from aged mares was significantly less than that achieved with the oocytes of younger mares.[198] Research has shown that embryo recovery rates are considerably lower in aged mares, and that significant losses occur before day 14 of pregnancy.[192,199–201] Ball, Hillman, and Woods have provided evidence to suggest that the uterine environment may not be the only reason for subfertility in some mares. Embryos collected from normal mares resulted in similar pregnancy rates in fertile and subfertile recipients (significant uterine pathologic condition) at day 28.[202] In a reversal of study design, embryos were collected from the oviducts of normal and subfertile mares at day 4 after ovulation and then were transferred into normal recipients. Pregnancy rates were lower in those normal mares that received embryos from the subfertile donors.[199] Thus although the uterine environment may have a delayed effect on embryonic and fetal loss, oocyte quality and oviductal influences apparently play a significant role in the problem of subfertility and early embryonic loss in mares.[203] In practice, embryonic losses that may be detectable between days 14 and 40 can range from 10% to 15% in young, well-managed mares to 25% or 30% in aged mares.[194,204] The presence of endometrial inflammation and uterine fluid accumulation have a detrimental effect on the early embryo survival and can increase the likelihood of early pregnancy loss greatly.[205,206]

16.8.4.2

EARLY FETAL LOSS

Formation of the endometrial cups is a defining moment regarding early pregnancy loss in mares. If the embryo dies before day 35, then the chorionic girdle cells do not invade the endometrium and the endometrial cups do not form. These mares should return to normal estrous cycle activity and may be bred successfully again during the same breeding season. However, if the fetus is lost after day 40, the endometrial cups irreversibly are established.[3] Thus if one performs an assay for eCG (MIP test) after the endometrial cups form, one will obtain a false-positive result for pregnancy until the endometrial cups are sloughed between days 120 and 140 after the original conception occurred.[3] Retention of the endometrial cups after fetal loss results in erratic estrous behavior, unreliable follicular development, and unpredictable ovulation. Thus this unique physiologic mechanism typically prevents mares suffering fetal loss after endometrial cup formation from being bred back during the current breeding season.

The exact mechanism that causes most pregnancy losses in the mare remains to be elucidated.[32,37,207] 1087
Beyond day 40 the secondary corpora lutea receive powerful luteotrophic support from eCG and from days 1088
80 to 100 until term, the supply organ (placenta) and target tissues (endometrium and myometrium) are in direct contact with each other over their entire surface. A paucity of evidence shows that a deficiency of progesterone production is a cause of pregnancy loss in the mare.[80] Certainly, fetal death may follow uteroplacental insufficiency or an overwhelming sepsis.[207] In recent years, a broad consensus has developed that the inflammatory mediator $PGF_{2\alpha}$ may play an integral role in many cases of fetal death.[85] Prostaglandins are well known to be luteolytic.[3] Thus in the first 70 to 80 days when the pregnancy depends on primary and accessory progesterone production of the corpora lutea, the pregnancy is especially susceptible to the luteolytic effects of prostaglandins. However, one should remember that repeated exogenous prostaglandin injections may be required to terminate a pregnancy electively once the endometrial cups have formed, because some of the immature accessory corpora lutea may not be developed sufficiently to respond to the first prostaglandin injection. Another probable abortogenic feature of prostaglandins may be myometrial hypermotility, which may be associated with placental inflammation or high systemic levels of prostaglandin.[208]

Studies by Daels and colleagues have demonstrated that an early pregnancy may be lost following prostaglandin-induced luteal deficiency associated with endotoxemia.[209–211] The detrimental effect of the endotoxin could be prevented only if a cyclooxygenase inhibitor (flunixin meglumine) was administered before clinical signs of endotoxemia were evident.[65,210,212,213] Thus although gram-negative septicemia and endotoxemia associated with many gastrointestinal crises are known to result in elevated levels of inflammatory mediators, any pregnancy-sparing effect of prostaglandin inhibitors is likely to be effective only if antiinflammatory agents such as flunixin meglumine are administered in the acute phase of the disease.[207] Because a healthy fetoplacental unit can produce enough progesterone to sustain the pregnancy after 80 days of gestation, the concept of prophylactic altrenogest past 3 months of gestation is controversial.[65,80,85,142,214]

Although recent in vitro studies suggest that progesterone may not be the primary regulator of myometrial quiescence, in situations in which elevated prostaglandin levels are likely, clinical justification appears adequate at present for providing exogenous progestagen support for high-risk pregnant mares.[148] Based on current knowledge, the administration of a double-dose (0.088 mg/kg s.i.d.) of altrenogest is suggested during the acute phase of a medical or surgical condition when prostaglandin levels are likely to be elevated.

[149] If the condition warrants muzzling the mare (nil per os), then short-term use of progesterone-in-oil (150 to 250 mg intramscularly every 24 hours) is warranted. This approach is based on further work by Daels and colleagues that showed that progestin treatment could prevent abortion at 3 to 5 months of gestation if a higher dose (0.088 mg altrenogest per kilogram) was administered.[65,142] Abortion did not occur in five of eight mares treated with progesterone and eight of eight mares treated with altrenogest, and endogenous $PGF_{2}\alpha$ secretion was inhibited, compared with values in aborting mares.[142] The researchers concluded that circulating progestagen concentrations may play a role in the outcome of pregnancy during prostaglandin-induced abortion.

That separation of the chorioallantois from the endometrium disrupts local endocrine function seems logical.[215] The fetoplacental unit does attempt to compensate for this placental dysfunction by increasing progesterone production.[216] However, endotoxemia may cause deleterious effects to the placental circulation and potentially disrupt vital steroid metabolism within the fetoplacental unit.[217] Thus administration of flunixin meglumine to pregnant mares is indicated early in the course of any condition in which endotoxemia is possible.[212,218,219] If a late pregnant mare develops a surgical colic condition, then the fetus is not only at risk from the maternal endotoxemia that can be associated with gastrointestinal crises but also from any maternal hypoxic episodes that may occur during anesthesia.[217,218,220,221] Acute enteritis or colitis in a pregnant mare also can result in abortion because of the effects of endotoxemia.[220,221] Because maternal hypoxia has been shown to be a risk factor for abortion, one must avoid intraoperative hypoxia if a pregnant mare requires surgery.[220] One can expect 16% to 20% of mares to abort after colic surgery, but superior intraoperative ventilatory techniques may reduce this risk.[220,221] Stage of gestation and duration of anesthesia are less critical factors provided that maternal oxygenation is adequate.[222] Apparently, aberrations in the cardiovascular and metabolic status of the mare and fetus are more detrimental to pregnancy maintenance than the actual medical or surgical condition.[219]

16.8.4.3 PLACENTITIS

Placentitis is a major cause of abortion in mares during the latter part of pregnancy.[181,223] Placentitis tends to be a sporadic, individual mare problem that seldom has any lasting effect on mare fertility.[224] Bacterial (β-hemolytic streptococci, *Escherichia coli, Pseudomonas aeruginosa, Klebsiella pneumoniae*) and fungal (*Aspergillus* spp.) organisms may be incriminated.[35,215,225–228] Ascending infections are especially common and result in inflammation and detachment of the placenta in the area surrounding the cervical star. The 1088
cervix is almost invariably softened, with purulent exudates draining into the vagina.[215,226,227] Thus one 1089
should examine this part of the fetal membranes closely whenever a mare aborts. The vestibular sphincter and vulvar lips are important barriers to ascending infections, and many aged mares require a Caslick procedure to reduce the likelihood of ascending infections. Hematogenous infection of the placenta is also possible.[226,227] *Leptospira* spp. induce a diffuse placentitis with large numbers of spirochetes in the placental tissues.[229,230] A unique form of placentitis has been reported as a sporadic cause of abortionand weak foals in central Kentucky over the past decade.[181,223,229,231,232] A review of nocardioform placentitis cases over a 9-year period (1991 to 1999) revealed that of the farms that had cases, 83% had two or fewer over the 9 years and 66% of the farms had only a single case during that time.[232] The causative organism recently was identified as *Crossiella equi*.[233,234] This bacterium is responsible for nocardioform placentitis and is one ofthe few actinomycetes known to cause animal disease. Although numerous gram-positive branching bacilli

are visible on histologic sections, the bacterium is seldom present in fetal tissue.[230,232] In vitro testing has demonstrated that the nocardioform bacterium is susceptible to sulfonamides and trimethoprim.[230] This combination is an ideal choice for systemic medication of a pregnant mare when placentitis is suspected because these antimicrobial agents are known to gain acceptable levels in the fetal fluids.

Although nocardioform placentitis was first diagnosed at the University of Kentucky in 1986, this type of placentitis has not been confirmed elsewhere in North America or in other countries.[230,234] Although the organism has been suggested as gaining access to the uterusat breeding, this unusual form of equine placentitis does not become apparent until the latter part of gestation.[224] The initial lesion is localized in the cranioventral aspect of the uterine body, extending cranially onto the base of the horns and circumferentially around the placenta.[235] Outcomes vary from abortion to birth of a normal foal. Some foals are premature, whereas others are delivered at term but are stillborn or weak and compromisedwith a malnourished appearance.[230,235] Most affected mares appear normal, although many display signs of placentitis (premature mammary development and lactation).[224,230,232,235] Vaginal discharge is not a feature of this condition because the area around the cervical star is not involved. Once the fetus has been expelled, these mares soon clear the infection with no adverse effects on subsequent fertility.[230,232] On examination of the fetal membranes, a line of demarcation is obvious between diseased and normal tissue, with the affected area being covered by a characteristic thick, brownish-tan mucoid material.[230] The underlying chorionic villi are reduced in size, and in the central portion of the lesion the chorionic surface may be denuded completely.[235]

The exact cause of fetal expulsion is not known, but placental thickening and separation from the endometrium are consistent features in many abortions.[181] Placentitis is detrimental to the pregnancy not only because it disrupts nutrient exchange but also because of the release of inflammatory mediators. Thus antiinflammatory medication (flunixin meglumine at 1.1 mg/kgor phenylbutazone at 4 mg/kg every 12 hours) is indicated.[208] Placentitis associated with early abortions tends to be acute, with the fetus succumbing to bacter-emia. Broad-spectrum antibiotics that have been recommended include trimethoprim-sulfadiazine (15 to30 mg/kg p.o. every 12 hours), procaine penicillin (30,000 IU/kg every 24 hours) and gentamicin(6 mg/kg every 24 hours), and ceftiofur (1 to 5 mg/kg every 12 hours).[208] Gentamicin is undetectable in the plasma of newborn foals after mares are treated with the antibiotic (6.6 mg/kg) an hour before parturition. Thus gentamicin apparently does not cross the placenta of mares at term.[236]

Abortions later in gestation tend to be associated with chronic placentitis and severe tissue reaction that results in uteroplacental insufficiency.[229,232] If the localized production of high concentrations of prostaglandins stimulates the formation of gap junctions, then the subsequent hypermotility may impede placental blood flow as the uterus contracts.[85] Impeded blood flow reduces fetal oxygenation and increases fetal stress. Because progesterone is known to inhibit gap junction formation, a clinically valid conclusion is that progestin supplementation may be beneficial when one suspects uteroplacental inflammation. This is the rationale behind the current recommendation to treat suspect placentitis cases witha double dose of altrenogest (0.088 mg/kg every24 hours).[85,208,216] However, one must understand that at this time the practice is controversial, and although the treatment probably does no harm, the expense of long-term progestin supplementation may not be warranted.[80] Recent studies suggest that measurement of relaxin levels may serve as a useful means of monitoring placental function and treatment efficacy in the mare.[237]

The rationale for other treatment regimens is based on extrapolations from the human literature and application of sound reasoning for the potential efficacy of a particular drug. Scientific investigation in this

areais needed desperately. Many equine clinicians havebeen advocating the use of an orally administered β_2-sympathomimetic drug (clenbuterol) to suppress uterine motility.[208,238] In the United States the product is marketed as an oral formulation to treat chronic obstructive pulmonary disease. Research is needed to determine what oral dose of this bronchodilatory compound, if any, is actually effective on the gravid uterus. 1089
Inthose countries where an intravenous formulation is available, research has shown that a 300-μg 1090
intravenous dose of clenbuterol reduces uterine tone for approximately 2 hours.[239–241] The administration of pentoxyfylline (7.5 mg/kg p.o. b.i.d.) is recommended, based on its use for treating tissue ischemia in human beingsand its ability to modulate the inflammatory process.[208,242] Pentoxifylline increases erythrocyte flexibility. Inflammation-driven uterine hypermotility may impede circulation in the placental capillary bed, and pentoxifylline is thought to increase fetal oxygenation by facilitating blood flow.[243,244]

16.8.4.4 LEPTOSPIROSIS

Leptospirosis has been incriminated as a sporadiccause of placentitis, abortion, and premature births in horses.[181,223,231,245–256] Leptospiral infections may cause abortions in the latter part of gestation, generally with no premonitory clinical signs, and occasionally an infected premature or full-term weak, icteric foal.[245,247,250,251,253] The placenta is edematous, with a necrotic chorion covered with a mucoid exudate.[230] The gross placental lesions are associated with thrombosis, vasculitis, and inflammatory cell infiltrates. The spirochetes tend to be numerous and are demonstrated readily in the stroma and villi of the placenta.[253,257] A microscopic agglutination test on fetal fluids (heart and body cavities) or maternal serum is likely to reveal a high titer (1:6400 to 1:819,200 or greater).[230,247] One may detect leptospires in the fetus by the fluorescent antibody test, silver staining, or darkfield microscopy.[230] One should submit the fetal kidney for a fluorescent antibody test because it yields the highest percentage of positive results. The kidney is also the best tissue for culture.[230,247] If one intends to submit urine from an infected mare (fluorescent antibody test or darkfield), one must obtain collection instructions and appropriate transport medium from the diagnostic laboratory.[230] One must obtain the specimen before administration of any antimicrobial therapy.

Although L. interrogans serovar *bratislava* is the serovar most commonly isolated from aborted fetuses in Northern Ireland, in North America most leptospiral abortions have been associated with the *pomona* serogroup, and occasionally the serovars *grippotyphosa* and *hardjo*.[245,247,249] Equine leptospiral infections previously reported as being *L. pomona* are now thought to be identified more correctly as L. interrogans serovar *kennewicki*.[230] In North America, pregnant mares are considered to be incidental hosts that become infected after exposure from maintenance hosts (i.e., wildlife such as skunks and raccoons for serovars *kennewicki* and *grippotyphosa* and cattle for serovar *hardjo*).[230,245,247] Infected mares may shed leptospires in the urine for up to 14 weeks. Thus therapy aims at preventing urinary shedding and possibly prophylactic treatment of pregnant in-contact mares that have high titers.[230] A combination of penicillin (10,000 to 15,000 IU/kg intramuscularly) and streptomycin (10 mg/kg intramuscularly) every12 hours for 1 week has been recommended, but streptomycin no longer is used widely in equine practice.[230,252,258] High doses of penicillin G potassium (20 million units intravenously every 12 hours) may be effective in preventing infection of a fetus if the mare has a high titer.[258] The dosage and duration of treatment appear to be important. Oxytetracycline (5 to 10 mg/kg) also has been suggested, but it was less effective at preventing urinary shedding of leptospires in all cases tested (five of seven infected mares).[230,252,258] No approved vaccine is available to prevent leptospirosis in horses in North America. One should attempt to prevent direct contact between maintenance hosts and pregnant mares and also to avoid exposure to infected urine from

these species (e.g., contaminated water and feed). Vaccination of cattle with a multivalent vaccine if they are present on the same property as pregnant mares may be prudent.[230]

16.8.4.5 MARE REPRODUCTIVE LOSS SYNDROME

In the spring of 2001 the equine breeding industryin central Kentucky was faced with reproductive crisis. Mares were foaling prematurely with premature separation of the chorioallantois (late-term “red bag” abortions), many mares that were 45 to 80 days pregnant suffered acute fetal loss, and an unusual number of weak foals were born.[259,260] The epidemic became known as the mare reproductive loss syndrome (MRLS). Some 318 aborted fetuses were submitted to the diagnostic laboratory between April 28 and May 8, 2001.[259] Fortunately, in the Kentucky epidemic of 2001, no contagious infectious cause was identified, and the condition became self-limiting as the breeding season progressed. Veterinarians and scientists involved in the epidemic considered the possibility of mycotoxins, ergot alkaloids, phytoestrogens, and even cyanide from wild cherry tree foliage. An extensive epidemiologic study was performed subsequently to identify risk factors that predisposed mares to MRLS.[259,260] At the time of writing, environmental toxic agents remain the primary suspect, with increasing attention being focused on the eastern tent caterpillar.[260]

The state diagnostic laboratory was inundated with late-term aborted fetuses, and practitioners identified approximately 2000 early fetal losses.[261] Many of these abortions were detected during what should have been a routine fetal gender determination. An initial questionnaire determined that during the peak period of MRLS in the spring of 2001, some 20% of mares that had been confirmed pregnant at 42 days were
determined subsequently to have suffered fetal loss by 60 days.[259] Approximately 500 late-term abortions 1090
were reported in central Kentucky; the Appalachian region to the north also reported a high number of 1091
similar cases. The author investigated reports of more than 150 late-term abortions in southeast Ohio during the spring of 2001. Reports of weather patterns and an unusually high emergence of eastern tent caterpillars *(Malacosome americanum)* were identical in the central Kentucky and southeast Ohio regions.[262] Results of the initial Kentucky survey confirmed that mares bred in February (45 to 80 days pregnant in late April or early May) were at high risk for fetal loss.[259,260] Mares that were not exposed to eastern tent caterpillars were not at risk, and feeding of hay to mares outside appeared to have been protective. Multiple breeds of horses were affected by MRLS. Smaller numbers of horses of different sexes and ages were diagnosed with pericarditis and unilateral uveitis during the same period.[260]

A study in 2001 involving 288 pregnant broodmares reported an early fetal loss rate of 25%, with a median gestational age at the time of fetal loss being 77 days. In this study early fetal loss was defined as being the loss of a fetus that was viable at 40 days of gestation but was subsequently lost by 5 months of gestation.[261] Although one could assume that maiden and barren mares were most affected because these horses would have been bred soon after the official season began in mid-February, management practices related to housing of mares with foals at foot may have reduced exposure to the toxin in this latter group.[260,261] What is less easily explained perhaps is the fact that fetal losses were significantly greater in mares of 10 years of age and younger.[261] The MRLS in 2001 in central Kentucky cost the local economy millions of dollars, and its effects were manifest in a reduced foal crop in the 2002 season. Most affected mares failed to resume normal cyclic activity until after the official breeding season had closed because endometrial cups had been formed before the MRLS fetal losses in the spring of 2001.

16.8.4.6 VIRAL ABORTIONS

Although equine infectious anemia is not regarded as an abortigenic disease per se, mares may abort because of the systemic effects of this virus.[263] Equine viral arteritis is a venereal disease that can be transmitted in the semen of asymptomatic (shedding) stallions.[264–267] However, the most common mode of transmission is through respiratory infection, and equine viral arteritis can cause abortion if infected animals come into contact with pregnant mares that are in the later stage of gestation (5 to 10 months).[266,268,269] Clinical signs vary but may include fever, conjunctivitis, nasal discharge, and dependent edema associated with the vasculitis.[267,269–271] Often the disease goes undetected because the clinical signs are mild or subclinical and may be clinically indistinguishable from other respiratory infections.[272] Transplacental infection of the fetus follows the development of myometritis, with degeneration of the myocytes and infiltration ofthe mononuclear cells. Epithelial cells of the endometrial gland show sporadic degeneration. The placentae are edematous, and one may observe degenerated fibroblasts in the subvillous layers. Lesions in the fetal tissue include an atrophy of the lymphoid follicles in the spleen and lymph nodes with degenerated lymphocytes. Immunofluorescence can detect equine arteritis virus antigen in the myometrium and the endometrial gland in the dams, in the subvillous layer of the placentae, and in the aborted fetuses. One may recover the virus from the uterus and fetus, but the placenta is likely to yield the greatest amounts of the virus.[273] One may control the disease by an effective vaccination program and screening tests (polymerase chain reaction, microneutralization, and enzyme-linked immunosorbent assay).[264]

The number of abortions caused by equine herpesvirus 1 (EHV1) infections has declined over the past 2 decades, and isolated abortions rather than abortion stormsare now a more common feature of this disease. In the Thoroughbred mare population of central Kentucky the number of EHV1 abortions per 1000 pregnant mares has remained below 5 since 1977, despite the mare population doubling in size.[274] This low abortion rate is due to widespread adoption of stringent vaccination programs combined with improved management practices on broodmare farms. Pregnant mares should be vaccinated with an approved vaccine at 5, 7, and 9 months of gestation. On many farms mares also are vaccinated at 3 months. New arrivals should be isolated for 3 weeks, and groups of pregnant mares should be isolated by stage of gestation. Segregation of pregnant mares from weanlings and other horses is especially important.[275]

Although EHV1 is often a subclinical respiratory infection in the mare, it can infect the fetus during a viremic episode and cause abortion because of rapid detachment of the placenta.[276] In these cases the endothelial cells in the endometrium and allantochorion are often virus-infected, with accompanying vascular lesions. The fetus can be infected via the chorionic vasculature or by inhalation of infected amniotic fluid.[277,278] Blood-borne viremic lymphocytes spread the infection from primary sites of replication in the respiratory tract and draining lymph nodes to the pregnant uterus.[279] The abortion may occur soon after the mare is infected but also may occur after several weeks have elapsed. Thus maternal serologic testing is of little diagnostic value.[280] Although EHV4 (formerly EHV1, subtype 2) occasionally is incriminated, EHV1 is responsible for mostlate gestation (>7 months) herpesvirus abortions.[281] The aborted fetus is fresh, with copious amounts of pleural and peritoneal fluid. The trachea may contain a fibrin clot. Small necrotic foci 1091
may be discernable on the swollen liver. A hyperplastic, necrotizing bronchiolitis may be visible in lung 1092
sections, and large intranuclear eosinophilic inclusion bodies are a characteristic histologic lesion. Although vaccination is practiced widely, owners should be aware that the protection is not absolute. If a pregnant mare is exposed to infected animals that recently have been to a show or that are returning from a training

facility, the possibility is that any protective immunity that the vaccine may have provided will be overwhelmed. Abortions have been associated with reactivation of latent virus that was induced by transport stress.[282] Thus a history of regular vaccination of an aborting mare does not eliminate the possibility of a herpesvirus abortion. Informed management practices are essential to minimize the chances of reproductive loss. One always should submit tissue samples for confirmation and should implement sanitary and isolation protocols. Neutralization tests, indirect immunofluorescence tests, and polymerase chain reaction tests and virus isolation are useful for EHV1 diagnostics. Antigen detection combined with virus isolation and polymerase chain reaction tests from fetal lungs gives reliable results.[283] More detailed reviews have been published.[225,284]

16.8.4.7 NONINFECTIOUS CAUSES OF ABORTION

In North America the incidence of twin abortions has dropped significantly because of early intervention after ultrasonographic diagnosis of a multiple pregnancy.[66,181] Before the widespread adoption of this technology, twin abortions were a major cause of fetal loss.[35] The type of placentation in the mare (diffuse, microcotyledonary) makes it highly unlikely that a twin pregnancy will be carried to term. Obviously, a finite endometrial surface area is available for allantochorion attachment. The more common unicornuate twin vesicles are a problem because one conceptus inevitably is restricted to the proximal aspect of the gravid horn.[16,204] Thus the two conceptuses are literally in a deadly competition for adequate nourishment and subsequent placentation. If the twin pregnancy is maintained until the latter part of gestation, the nutrient demands of the rapidly growing fetuses outstrip the placental attachments. Fetal growth is such that nutrient demands may be met until the latter half of gestation, when the considerable fetal development in the last trimester usually requires more exchange capability than the smaller placenta provides. The fetus becomes stressed as it becomes progressively emaciated, and ultimately dies.[183] Death of one or both fetuses is followed by abortion, with the characteristic avillous areas on the fetal membranes confirming the amountof placental disruption.[36,170,181] Affected mares develop premature mammary enlargement and may “run” milk before aborting.[36,285] Transabdominal ultrasonographic evaluation can be useful to confirm the diagnosis at this late stage. The area of apposition of the two chorioallantoic membranes (twin membrane) can be a useful aid for ultrasonic diagnosis of twins even in late pregnancy.[183] Twin abortions in the last few months of gestation are likely to cause a dystocia. Bicornuate twins are more likely to survive because each membrane can attach to an entire horn and one side of the uterine body, but the resulting foals are likely to be stunted because of intrauterine growth retardation.[4,36] The live birth of twin foals is extremely uncommon, and many of these neonates do not survive.[175] The mares are prone to fetal membrane retention and may be difficult to rebreed. Thus, not surprisingly, the equine breeding industry has tried always to avoid twin pregnancies.

Ultrasonographic studies of fetal mobility have helped explain the characteristic twisting that is a feature of the normal equine umbilical cord.[4,286–289] Unlike the situation in ruminants, the equine amnion floats freely within the allantoic fluid. Fetal rotation within the amniotic cavity, and amniotic sac rotation within the allantoic fluid, results in the characteristic twisting of the equine umbilical cord.[286,290] A recent report reviewed 168 cases of umbilical cord torsion from the University of Kentucky Livestock Disease Diagnostic Center representing 6.0% of equine fetus submissions over a 5-year period.[291] The gestational age of the fetuses ranged from 5 to 10 months, with a mean of 7½ months. The mean umbilical cord length for full-term Thoroughbred foals is reported to be 55 cm.[292] Umbilical cord lengths in the Kentucky torsion cases varied from 62 to 125 cm.[291] The average length of the affected cords (96 cm) exceeded that described in another

abortion study by almost 10 cm.[293] The cords tended to be highly twisted with areas of constriction, edema, hemorrhage, and thrombosis and fluid-filled sacculations. The fetuses were slightly to moderately autolyzed. This is consistent with fetal death before abortion. Urinary bladder dilation was noted in some cases, presumably because of obstruction of urachal outflow. The most consistent histopathologic finding was deposition of calcified material in the blood vessels of the chorioallantois.[291] At this time, no evidence appears to suggest that if a mare aborts because of umbilical torsion, the risk for future umbilical cord complications increases. Another complication that can be associated with an excessively long cord is strangulation. In this instance the cord becomes tightly wrapped around the fetal body or extremity, often causing a deep groove and edema of surrounding tissues.

16.8.5 Gender Determination (Fetal Sexing)

The advent of fetal sexing has permitted early gender determination to influence the value of the pregnant mare. 1092
Factors that may vary depending on the predicted sex of the foal include choice of state for foaling, appraisals 1093
and insurance coverage, sales reserves, bookings for stallion service the next season, and retention or sale of the mare.[294] Gender determination of the equine fetus can be accurate using transrectal or transabdominal ultrasonography.[294–296] One should certify fetal gender only when the identifying structures have been delineated clearly and the accuracy of the determination is guaranteed. Accurate determination of fetal sex may be difficult or impossible in some cases because of excessive mare and fetal movement or the fetus being located too deeply to permit adequate imaging. Although tranquilization (e.g., xylazine and butorphanol tartrate) is used sometimes, it may cause the uterus to relax and drop away from the examiner.[294,297] A 5.0-MHz linear array transducer is adequate for transrectal gender determination, but a 3.5-MHz transducer ensures the depth of penetration that is required to obtain transabdominal images.[155]

Gender determination is based on ultrasonographic assessment of the location of the genital tubercle, an embryologic structure initially located between the rear limbs in both sexes. The genital tubercle differentiates into a clitoris or a penis and has an ultrasonographically distinctive, hyperechoic, bilobulated appearance in both sexes. Curren[297] reported that the optimal time for gender determination is between days 59 and 68, and Holder[294] concurs that a day 60 to 70 window is the ideal period. A second ideal period for gender determination may be between days 110 and 120 because the genitalia are now well developed and the fetus tends to be more accessible again. After this time the increasing depth of the uterus means that one may not be able to make a diagnosis if the fetus is in a anterior (cranial) presentation at the time of the examination.[294] When one uses the transabdominal approach, the optimal window of time in both sexesis between 100 and 220 days of gestation.[295,296] Thereafter, identification of the anatomic structures required to make an accurate gender determination may become increasingly difficult. Detailed instructions for fetal sexing by ultrasonography have been described.[294–297] Transabdominal gender identifications based on the presence of the penis and prepuce in males and mammary glands and teats or fetal gonads in females can be accurate.

16.8.6 Monitoring Fetal Well-Being

One should suspect that mares that develop premature mammary enlargement (with or without lactation) have placentitis. A reduction in plasma relaxin levels may indicate placental compromise, because relaxin is produced by the equine placenta.[105,109–111,114,237,298–300] Low relaxin levels in late pregnancy have been associated with various causes of placental dysfunction, including fescue toxicosis, oligohydramnios, and placentitis.[301] Measurement of an equine fetal protein and estrone sulfate levels in maternal plasma have not

proved useful for early detection of fetal stress associated with medical and surgical colics.[77,78,302–305] Although pathologic conditions ofthe placenta have been correlated with increased plasma progestin concentrations in some studies, others have not detected differences in plasma progestin concentrations in mares with impending abortion and mares with normal pregnancies when monthly blood sampling was performed.[33,87,97,306–308] Pregnant mares that have experienced colic or uterine torsion and that have progestagen levels less than 2 ng/ml are at high risk for fetal loss.[77] Obtaining serial samples from a mare suspected of having placentitis is recommended. This may help to identify a clinically useful trend in progestagen concentrations.[77,208]

One must use strict hygienic procedures when using a vaginal speculum on a mare with a high-risk pregnancy, because one breaches the first two barriers to the pregnant uterus (vulvar lips, vestibular sphincter). Mares at risk for abortion often have a moist, hyperemic, relaxed cervix. Even if a vaginal discharge has not been reported, many of these mares have a purulent cervical dischargeif placentitis is present. However, although cervical softening and vaginal discharge are often present if the infection is localized around the cervical star, in the case of nocardioform placentitis the lesion does not involve the cervical star, and vaginal discharge is conspicuously absent.[230,232,235] Thus although transrectal ultrasound is a useful aid for diagnosing ascending placentitis, the site of the nocardioform lesion makes it of limited diagnostic value in these cases.[238] Transabdominal examination of the ventral uterus may reveal separation of the chorioallantoic membrane from the uterine wall, often with evidence of inflammatory exudate accumulation between the two surfaces. Placentitis and associated placental edema results in a thickened uteroplacental image. The average uteroplacental thickness on a transabdominal ultrasound image should be between 9 and 14 mm.[309,310] If the uteroplacental thickness exceeds 2.0 cm in late gestation, then a pathologic condition of the placenta is likely to be present.[310,311]

Transabdominal ultrasonography of late pregnant mares has become a routine diagnostic aid for evaluating fetal well-being.[285,308,310,311] Although the 5.0-MHz linear array transducer is ideal for transrectal reproductive ultrasonography, its shallow depth of penetration (~10 cm) limits its usefulness for transabdominal examinationsin late pregnant mares. If the mare does not have a pronounced plaque of ventral edema, the 5.0-MHz transducer often is sufficient to image the uteroplacental unit and some of the fetal fluids. A 3.5- or 2.5-MHz curved linear array or sector-scanner transducer is best for transabdominal examinations because these 1093
can penetrate to a depth of 20 and 30 cm, respectively.[156,312] Although one may image the 70- to 90-day fetus 1094
from the ventral abdomen of the mare, just cranial to the mammary gland, the late gestation gravid uterus extends along the ventral abdomen to the xiphoid.[285,309–313] By the ninth month of gestation the fetus should be in anterior (cranial) presentation and dorsopubic or dorsolateral position.[2,287,313] Thus in late gestation the fetal head should be positioned near the pelvis of the mare. An abnormal presentation, or the presence of twins, is possible if one detects a fetal head along the ventral abdomen during late gestation.[312] A more detailed examination is indicated in such cases. The posture of the extremities varies with fetal movement.[313]

One must follow a standardized methodology when scanning the uterus from the ventral abdomen, starting just cranial to the mammary gland of the mare and moving cranially to locate the fetal thorax. The ribs cause multiple acoustic shadows that delineate the thoracic cavity. A complete examination of the fetus and uterus involves scanning cranially to the xiphoid in multiple parasagittal planes and then scanning from left to right sides of the abdomen in multiple transverse planes.[312] Transabdominal ultrasound examination is an important diagnostic tool when one attempts to identify the presence of twin fetuses in late gestation. Identification of the nongravid horn can be useful to help rule out the possibility of twins. Often, obvious size discrepancy serves as

confirmation that twins are present. In other cases, one thoracic cavity does not contain a beating heart, confirming that one of the twins has died already.

In a normal pregnancy most of the fetal fluids are within the allantoic cavity. The amnion is imaged as a thin membrane that surrounds the fetus and actually lies in close contact with the fetus over much of its body. The amniotic membrane divides the imaged fetal fluid into two distinct cavities that one can see most easily around the fetal neck, shoulder, thorax, and foreleg. Typically, one images the largest pocket of amniotic fluid where the forelimb and neck meet the thorax. The maximum vertical depth of amniotic and allantoic fluid, and the qualityof amniotic and allantoic fluid are useful guides to fetal well-being.[312] One should make any measurements of fluid depth as perpendicular to the uteroplacental surface as possible.[311,312] In the normal equine pregnancy the maximum ventral fetal fluid pocket depth for amniotic fluid is 8 cm and for allantoic fluid is 13 cm.[309,312] Extremes in either direction are not normal. Obviously deficient amounts of fetal fluid indicate placental dysfunction, and excessive amounts suggest a hydrops condition.[309,314] Reef suggests that fetal fluid quantities should be considered excessive if the maximal vertical amniotic fluid depth exceeds 14.9 cm or the maximum vertical allantoic fluid depth exceeds 22.1 cm.[312] The quality of the fetal fluid is scored from 0 (clear) to 3 (echogenic fluid with numerous particles).[311,312] For one to note echogenic particles in the fetal fluids is not unusual, especially during periods of fetal activity. These particles represent sloughed cells and proteinaceous debris.[310] An increase in the number of echogenic particles in late gestation may not be abnormal.[311] However, if one is monitoring a high-risk pregnancy regularly and one observes a sudden increase in fluid turbidity (grade 3), the prognosis is not good.[310,311] The clinician should consider the possibility of inflammatory exudates, meconium passage by a compromised fetus, or even hemorrhage. One should remember that hippomanes (allantoic calculi) are a normal feature of the equine pregnancy. One may observe these structures on the ventral aspect of the allantoic cavity.[312]

An equine biophysical profile has been proposed as a guide to assessing fetal well-being and predicting perinatal morbidity and mortality.[310,311,315] Although a low score definitely indicates a negative outcome, higher scoresdo not guarantee the birth of a viable neonate.[312] Fetal breathing, heart rate and rhythm, fetal tone, and general activity are useful guides for evaluating fetal health and well-being. Thus one should avoid chemical sedation of the mare because commonly used drugs are likely to induce fetal bradycardia and suppress normal fetal activity. Fetal breathing is characterized by movement of the diaphragm between the thorax and abdomen, along with rib cage expansion, without any other movement by the fetus. One should monitor fetal breathing patterns forat least 30 seconds.[312,316]

When one monitors fetal heart rate and rhythm, scanning for only 10 or 15 seconds and then multiplying by a correction factor to obtain the number of beats per minute is not appropriate. Beat-to-beat variations and observation of periodic accelerations are important. Heart rate accelerations normally occur in association with fetal activity. Reef recommends that one make multiple measurements of fetal heart rate and assessments of fetal heart rhythm over a 30-minute period while evaluating the fetus, fetal fluids, and placenta.[312] Ideally, one should obtain three measurements with the fetus at rest and another three after periods of activity. Accurately monitoring the heart rate during periods of fetal activity is difficult, unless M-mode echocardiography equipmentis available.[312,313] Fetal heart rates vary with the stage of gestation and the amount of fetal activity at the time of the examination.[317–319] The fetal heart beat is normally regular and decreases from greater than 120 beats/min in midgestation to between 60 and 90 beats/min in late gestation.[309–311,313,317–321] Cardiac accelerations (20 to 40 beats/min above baseline) are normal if they are associated with fetal movement. [309,310,312] However, persistent tachycardia in the absence of fetal activity indicates fetal stress. A resting heart 1094

rate exceeding 104 beats/min indicates stress in a late-gestation fetus. A heart rate of less than 57 beats/min in a fetus that is less than 330 days of gestation and a rate of less than 50 beats/min in a fetus older than 329 days gestation should be considered abnormal.[311,312] A fetus suffering from hypoxemia has a slow heart rate, with minimal limb activity or fetal breathing, indicating central nervous system depression.[310–313] However, if the condition is chronic and ischemic conditions are developing, the fetus will become tachycardic despite a lack of fetal activity, which is a prelude to fetal demise. In terminal cases, extreme bradycardia ensues just before fetal death.[311,316] Although failure to observe fetal activity may be because of the stage of the normal rest/activity cycle, confirmation of a regularly beating heart at least confirms that the fetus is alive, which is a major advantage over transrectal fetal ballottement in which failure to detect movement can raise unnecessary concerns about fetal health.

If Doppler ultrasound equipment is available, one places the Doppler transducer directly over the site where one detected the best image by the ultrasound scan. One can record tracings of fetal heart rate and rhythm over time, usually intervals of 5 to 10 minutes.[322] Such tracings make analysis easier and serve as a permanent record of the fetal status at the time of the recording. If some question arises about the presence of twins after a transabdominal ultrasound examination, fetal electrocardiogram tracings may show two distinct fetal patterns.[320,321] Features of the electrocardiogram tracing that one should note include fetal heart rate and rhythm, accelerations and decelerations, complex polarity changes, and beat-to-beat variation. In the last weeks of pregnancy, fetal foals usually have a baseline heart rate in the range of 60 to75 beats/min. Transient low heart rates of less than60 beats/min are not uncommon. These troughs only warrant concern if they are not interspersed with accelerations. Likewise, transiently elevated rates around120 beats/min (occasionally >200 beats/min) are not abnormal, provided that they return to baseline. If the fetal heart rate is found to be less than 60 beats/min or greater than 120 beats/min during an observation period, then more frequent monitoring is justified to determine if the fetus is distressed. Beat-to-beat variations are normal, and a finding of no variability is an ominous sign. Maternal medications such as detomidine or butorphanol reduce fetal heart rate variability transiently.[316]

The fetus has tone if one observes it flex and extend the limbs, torso, or neck. Tone is poor or absent if the fetus appears flaccid. Fetal movements include partial to full rotation around the long axis of the fetus and less marked activity such as extension and flexion of the extremities. Fetal activity is rated on a scale from 0 to 3, with 3 being an active fetus. A score of 0 indicates that one noted no fetal movement during the examination period.[311,312] Long periods without noticeable fetal activity are cause for concern and should be evaluated along with information about the fetal heart rate and rhythm. The fetus may be distressed, suffering from advanced hypoxia, and have central nervous system depression.[310,311]

Fetal aortic diameter is correlated with the weight of the pregnant mare and with the final neonatal foal weight.[309–311] Thus one can use the weight of the pregnant mare to estimate what the fetal aortic diameter should be, using the regression equation ($Y = 0.00912 \times$ weight of pregnant mare in pounds $+ 12.46$) where Y is the predicted fetal aortic diameter (millimeters).[311,312] One then should measure the actual diameter of the fetal aortain the thoracic cavity as close to the fetal heart as possible.[309,311] An aortic diameter smaller than predicted may indicate a dysmature or growth-retarded fetus (intrauterine growth retardation) or twins. One measures the maximal thoracic diameter from the spine to the sternum over the caudal part of the thorax, and in a late gestation fetus the diameter should be 18.4 ± 1.2 cm. Thoracic diameter has been correlated with fetal aortic diameter and neonatal foal weight in high-risk pregnancies.[311,312] Foal girth measurements and hip height also have been correlated with fetal aortic diameter measurements.[310,312] Fetal biparietal measurements

and orbital diameters also have been used to estimate fetal size.[312] Decreased blood flow to the placental unit inhibits fetal growth, andone should suspect some form of chronic placental insufficiency on detection of small fetal size.

Transrectal ultrasonography provides an excellent assessment of the current status of the caudal allantochorion, and as such it is an invaluable aid for examining a late pregnant mare with signs of placentitis. An image of the ventral placental tissues in the area adjacent to the cervical star provides the ability to diagnose the early stages of ascending placentitis accurately[208] and may provide the best chance for successful medical intervention. Experienced clinicians are able to observe abnormal tissue thickness and even evidence of placental separation with an associated pocket of inflammatory exudate. Normal values for the combined thickness of the uterus and placenta have been established.[323] The combined tissue measurement is useful because it is difficult to determine exactly where the chorioallantoic membrane meets the endometrium. The area cranial and ventral to the cervix provides the most consistent measurement in normal mares, and this is the recommended site for any measurements. One should freeze the ultrasound image after locating the landmark vessel in the ventral uterine wall. One takes caliper measurements from the inner surface of the ventral uterine vessel to the edge of the allantoic fluid.[208] An established fact is that an increased combined thickness of the uterus and placenta any 1095
time from midgestation through until term indicates placental disruption and pending abortion.[306] If the 1096
combined thickness of the uterus and placenta exceeds 8 mm between days 271 and 300, 10 mm between days 301 and 330, or 12 mm after day 330, it indicates placental failure and impending abortion.[208]

Monitoring of fetal viability if one is maintaining a high-risk pregnancy by altrenogest supplementationis important. Although most nonviable fetuses will be aborted, reports have been made of mares retaining mummified fetuses when the mare was maintained on long-term progestagen supplementation.[189]

16.8.7 Complications in Late Gestation

Once confirmed to be at least 45 to 60 days pregnant, most mares can be expected to carry the fetus to term. The incidence of fetal loss after 100 to 120 days of gestation is low and accounts for only a small percentage of total pregnancy wastage. Fetal death and maceration is uncommon in the mare. However, the author has managed a case of macerated twins in a Draft breed mare that suffered no ill effects systemically. The mare was presented for evaluation only when the owner noticed a foul-smelling vaginal discharge.[324] Ventral body wall ruptures and uterine torsions are uncommon, and hydropsof the fetal membranes is an especially rare condition. Accurate diagnosis and appropriate management of these clinical cases can prevent the development of a life-threatening situation for the mare. If a ventral body wall rupture or uterine torsion is present, then the birth of a viable foal may still be possible, provided that the case is managed correctly.[325]

16.8.7.1 HYDROPS OF THE FETAL MEMBRANES

Hydrops is a condition of the last trimester, with the pregnancy developing normally until somewhere between 7½ months through term. Hydrallantoisand hydramnios are rare conditions that involve a pathologic accumulation of fluid within the allantoic and amniotic compartments, respectively. Normal volumes of allantoic fluid in mares vary from 8 to 18 L at term. In documented cases of hydrops the allantoic fluid volume ranged from 110 to 230 L.[326] Just as with cows, hydrallantois accounts for most dropsical conditions in the mare.[327–329] The pathophysiology of hydrallantois in the cow has been related to an abnormality of placentation, whereas hydrops amnion has been associated with a fetal head anomaly that precludes

swallowing.[159] Dysfunctional placentation may cause an increased production of transudate or disruption of transplacental fluid absorption. No abnormality of the fetus or fetal membranes is an apparently consistent characteristic of the condition in the mare. Bain and Wolfsdorf have incriminated a mild diffuse placentitis or endometrial vasculitis in some cases.[330] In a report on 15 cases, all of the mares were pluriparous and ranged in age from 6 to 20 years.[326]

Generally, onset of abdominal distention is sudden, and walking becomes difficult. The mare exhibits variable degrees of colic. Loss of appetite is progressive, and the mare may experience some difficulty in defecation. The increasing pressure on the diaphragm causes dyspnea, and the mucous membranes may appear cyanotic, especially when the mare is recumbent.[326] On physical examination the rectal temperature is normal, but the pulse rate is elevated. Palpation per rectum reveals characteristic findings. One should use copious lubrication and extreme caution because pressure from the large fluid-filled uterus will impede passage of the forearm. The feces tend to be covered with mucus because of prolonged passage through the lower gastrointestinal tract. The gross distention of the uterus means that the fetus is usually not palpable. Failure to detect the fetus by external ballottement further supports the diagnosis. Transabdominal ultrasound confirms the presence of excessive amounts of hyperechoic fluid. One should perform a thorough examination from both sides of the abdomen to eliminate the possibility of twins.[325]

One should advise owners that the condition is progressive and that the mare likely will not be able to sustain the pregnancy and deliver a live foal. Bain and Wolfsdorf have used a partial drainage technique in an attempt to manage some cases that were diagnosed within 2 to 4 weeks of term.[330] The mares receive abdominal support (belly band), intravenous fluids, broad-spectrum antibiotics, and antiinflammatory medication. The technique of slow, repeated drainage involves a major time commitment and would not be cost-effective for many cases. Fetal death may occur because of placental separation. A considerable risk for iatrogenic fetal infection following contamination of the fetal fluids also is apparent, despite attempts to perform the drainage technique in an aseptic manner. Thus despite heroic attempts in valuable mares, the fetus is likely to be lost in cases of hydrallantois.

In most cases, induction of parturition may be advisable before the condition of the mare deteriorates further. Continued abdominal enlargement predisposes the mare to prepubic tendon rupture,[331] and uterine rupture also has been reported.[332] Induction is not without risk (shock, dystocia), but the prognosis for survival of the mare is good, provided that appropriate supportive therapy is instituted. The prognosis for the reproductive future of the mare also may be favorable, provided that no untoward sequelae (cervical lacerations, retained fetal membranes, metritis) occur. Application of PGE to the cervix before induction may facilitate atraumatic 1096
fetal extraction.[333] In one report, six of eight mares that had previously developed a hydrops pregnancy 1097
subsequently became pregnant and delivered normal, healthy foalsat term.[326]

Before a therapeutic induction of parturition, one should wrap the tail, clean the perineal area, and insert an indwelling intravenous catheter. Large volume intravenous fluid therapy may become necessary if hypovolemic shock develops on discharge of the allantoic fluid.[325] In some cases, controlled drainage may be beneficial before inducing delivery. An added complication in hydrops cases is that the thickened, edematous chorioallantoic membrane may be difficult to rupture.[327] If digital pressure alone does not rupture the membrane, then one can use an endometrial biopsy forcep to bite a piece out of the chorioallantois. Some authors report that thelack of pressure from the atonic uterine wall resultsin minimal release of fetal fluid from the punctured chorioallantoic sac, but in the few cases with which the author has been involved, the release of fluid was massive once the chorioallantoic membrane was ruptured.[327,329] If insufficient fluid

release occurs, then one can introduce a sterile nasogastric tube into the uterus to begin controlled siphoning of fluid. An alternative technique is to introduce a thoracic trocar catheter through the cervix and to use a sharp puncture of the chorioallantois.[330] This approach permits one to remove the excess fluid by controlled drainage. Administration of intravenous fluids together with gradual removal of the excess allantoic fluid permits the cardiovascular system of the mare to adapt. Oxytocin and prostaglandin injections have been used in an attempt to abort in these cases.[327–329] Although oxytocin is considered widely to be the most efficacious method for routine induction of parturition, in hydrops cases the distended uterine musculature may not be able to contract effectively.[327,334] This uterine inertia is common, and gentle manual dilation of the cervix—or perhaps prior application of PGE—may be warranted.[333] Bain and Wolfsdorf have reported a smooth induction following two doses of cloprostenol administered30 minutes apart.[330]

The abdominal musculature may be weakened by stretching, and thus the typical stage II abdominal press may be compromised. Malpositioning and malpostures are common. The fetus may need to be extracted by assisted vaginal delivery, but one should take care so as not to traumatize the cervix by overzealous traction.[325] The expelled fetus generally is alive, and humane euthanasia is warranted. In one report, at least 50% of fetuses had some malformation.[326] One should add more oxytocin (1.0 IU per minute) to the intravenous fluids to promote uterine involution. One should expect retention of the fetal membranes, and appropriate treatment for removal of these membranes and prevention of the metritis-laminitis complex is indicated. One should monitor uterine involution by transrectal palpation and ultrasonography.

16.8.7.2

VENTRAL BODY WALL HERNIAEAND PREPUBIC TENDON RUPTURE

Apart from those with pathologic pregnancies, mares with ventral body wall defects are generally close to term. Damage to the abdominal sling of the pregnant mare may involve rupture of the transverse abdominis and oblique muscles, the rectus abdominus muscles, andthe prepubic tendon. The prepubic tendon attaches to the cranial border of the pubis.[325] Although breed (Draft mares) and age (older mares) may predispose a mare to development of the condition, in most cases the predisposing cause is not apparent.[331] The extreme abdominal distention associated with the hydrops condition may cause rupture of the ventral musculotendinous support. Defects in the ventrolateral abdominal wall are more common than complete prepubic tendon rupture.[331,335,336] In extreme cases the rupture may lead to hemorrhage, shock, and death.[337]

The most obvious clinical sign of an impending ventral body wall rupture is a thick plaque of ventral edema extending a variable distance cranial to the udder. However, ventral edema may be a normal side effect of late pregnancy and can indicate external trauma. The author has managed one case in which a large ventral swelling was associated with a massive hematoma that appeared to have originated from a kick. Mares in late pregnancy often develop a thick plaque of ventral edema that can extend from the udder to between the forelimbs. The edema is associated with the compressive weight of the gravid uterus on the venous and lymphatic drainageof the ventral abdomen. The presence of a hemorrhagic secretion in the mammary gland supports a diagnosis of tissue trauma rather than pregnancy edema. Unilateral edema is more indicative of damage to the ventrolateral body wall but may be associated with partial rupture of the prepubic tendon.[325] The extreme pain associated with progressive enlargement of a ventral body wall rupture causes a significant tachycardia that may not respondto analgesics. Pregnant mares with a ruptured prepubic tendon or ventral abdominal wall show signs of colic and generally are reluctant to move. If the prepubic tendon ruptures completely, the pelvis will tilt such that the tailhead and tuber ischii are elevated, and a lordosis will be

present. The mammary gland often is displaced craniad and ventrad because of loss of the caudal attachment to the pelvis. A rent in the abdominal musculature may be complicated by bowel incarceration.[325,331]

Confirmation of the tentative diagnosis can be difficult. Because one cannot always be certain that a rupture has occurred, one should confine mares with severe ventral edema to a stall, with exercise restricted to 1097
walking in hand. Palpation of the defect per rectum is usually not possible because of the advanced stage of 1098
the pregnancy. External palpation is also generally unrewarding because of the thickness of the edema, although one may note some crepitation of the ventral abdominal wall. The mare generally is extremely sensitive and resists palpation of the area.[325] Ultrasonographic examination of the posterior aspect of the ventral abdomen may be useful insome cases and can detect the presence of a bowel segment.[312,325,337] One often cannot assess the dimensions of the defect accurately until the fetus and fetal fluids are expelled and the ventral edema has subsided.[325]

Termination of the pregnancy may be the most humane treatment for the mare, for further tissue damage is likely to occur to some degree until parturition. In extreme cases the mare may eventually become recumbent. One also should consider the possibility of a segment of intestine becoming incarcerated in the defect. However, the present fetus may well be her last, and owners often request that an attempt be made to maintain the pregnancy to term. In these cases the treatment is essentially supportive. Antiinflammatory drugs help to alleviate the discomfort of the mare. An abdominal sling (belly band) made of canvas or padded leather or a snug abdominal bandage helps provide support for the ventral abdominal wall. In the author's experience, abdominal bandages tend to be purely cosmetic because they soon stretch and thus provide minimal long-term support. If one uses a sling, the area over the back must be well padded to prevent pressure necrosis because the purpose of this support is to transfer the weight of the gravid uterus to the vertebral column.[325] Reducing the bulk of the ration and feeding a mild laxative may help reduce the degree of abdominal exertion associated with defecation.[337]

Assistance with parturition should be available, for the mare is likely to experience difficulty in mounting sufficient abdominal pressure to expel the fetus. One should make arrangements for an alternate source of colostrum because ventral edema may preclude the foal from suckling. One should inform the owner that although in some cases surgical repair of the defect may be possible by mesh herniorrhaphy, rebreeding the mare may not always be advisable.[331] Some mares with small, unrepaired defects may foal subsequently without assistance, but one should consider the potential risk of further pregnancies exacerbating the condition.[337] Embryo transfer offers a viable alternative if this procedure is condoned by the relevant breed society.

16.8.7.3 UTERINE TORSION

Uterine torsion accounts for 5% to 10% of all complicated obstetric conditions in the mare.[338,339] The causes of uterine torsion in the mare are not well defined. The condition is much more common in cattle, and in that species a large term fetus has been implicated as a major risk factor. Most uterine torsions in cows occur at term, and most are thought to result directly from fetal positional changes during late first stage and early second stage of labor.[340] A striking difference between the mare and the cow is that more than 50% of uterine torsions in mares occur before the end of gestation.[338] In the author's clinical experience, most torsions occur before term and may occur as early as 8 months of gestation.[325] In fact, one recent report documented a case as early as 126 days of gestation.[341] Although Ginther has shown that the fetus is locked

into a dorsopubic position during the final months of gestation, it still is possible for the entire pregnancy (uterus and fetus) to rotate approximately90 degrees on the lower maternal abdominal wall.[4] This rotation occurs because any rotational movement of the caudal half of the fetus (pelvis and hindlimbs) by necessity involves the close-fitting uterus. In extreme cases this rotating action seems likely to lead to a clinical uterine torsion.[342] Owners who work closely with their mares may mention that they have observed excessive fetal movements in the flank area in the past day or two. In a recent study, 80% of term fetuses were in dorsosacral position when the uterine torsion was corrected. This suggests that fetal righting reflexes may have played a role in creating the torsion.[339] The author believes that vigorous fetal movements during the latter stages of gestation are likely to be a significant factor in the cause of uterine torsion in the mare.

The clinical signs that attract the owner's attention result from abdominal pain[325,343–346] and include restlessness, sweating, anorexia, frequent urination, sawhorse stance, looking at flanks, and kicking at the abdomen. When the veterinarian is first summoned, the signs may have been present for two hours, but sometimes for up to 3 days or more, especially if they are intermittentand moderate.[325,344] In mares that are close to term, the owner may assume that the signs indicate impending parturition. In more extreme cases the signs are more severe and may be associated with concurrent involvement of the small or large colon.[344,345] Veterinarians always should consider the possibility of uterine torsion when presented with a mild, persistent colic in a mare that is in the last trimester of gestation. Delay in making a definitive diagnosis increases the likelihood of fetal compromise.[325] Occasionally the condition may remain undiagnosed for several weeks.[347] In these instances an owner may have attempted treatment with analgesics that they have used for previous mild colic episodes.[325,343]

Palpation per rectum is essential to determine whether a uterine torsion is present.[325,343] The author is of the opinion that all late pregnant mares that display signs of mild to moderate colic warrant a thorough rectal 1098
examination to rule out the possibility of uterine torsion. Although vaginal involvement in the torsion is 1099
common in the cow, uterine torsions in the mare seldom cause detectable changes in the vagina.[325,340,344,347,348] Thus vaginal examination is generally not diagnostically useful. On palpation per rectum the clinician should aim to advance the forearm carefully while palpating for a taut band on either side of the rectum. The ligament on the side of the torsion tends to be more caudal and is palpable as a tight vertical band. As one advances the arm further, the opposite ligament will be palpable as it is pulled horizontally across the top of the uterus before being displaced ventrally. An accurate examination of the broad ligaments confirms the diagnosis, determines the direction of the torsion, and gives some idea of the severity of the torsion. A transrectal ultrasound examination is useful to evaluate the condition of the fetal fluids and to note if any placental detachment has occurred. One can gauge the degree of uterine compromise by notingthe thickened uterine wall and distended vasculature. Compression of the veins and lymphatics occurs before occlusion of the arterial blood supply. Thus the initial changes are associated with pooling of fluid within the uterine wall.[325] The compressive forces of the displaced broad ligaments may cause variable amounts of constriction of the small colon.[344,349]

One may use transabdominal ultrasonographic imaging to assess fetal viability (heart rate and rhythm) and to evaluate the condition of the fetal fluid. Abdominocentesis can provide prognostic information and guide the clinician in choosing a mode of correction.[350] Because obtaining peritoneal fluid from a mare in late gestation may be difficult, transabdominal ultrasonography is sometimes useful in locating a pocket of fluid. Uterine rupture can be a complication of uterine torsion in the mare.[344,351] In the author's experience, mild uterine torsions or those of short duration do not alter the color, cellularity, or total protein content of the

peritoneal fluid. Severe torsions or misdiagnosed cases that are more chronic may develop significant uterine compromise that results in changes in the composition of the peritoneal fluid. Any alterations in the composition of the peritoneal fluid may indicate the presence of a compromised or ruptured uterine wall.[350] A flank laparoscopic examination can confirm the condition of the uterine wall.[352] This information facilitates an informed choice of surgical approach or perhaps supports a decision for euthanasia if economic considerations preclude surgical intervention.

If the mare is at term and the cervix is dilated sufficiently to permit passage of a well-lubricated arm into the uterine body, then one may possibly reach the fetus. One should grasp the fetus ventrolaterally and then rock it back and forth until sufficient momentum is achieved to continue up in an arc. This manipulation should roll fetus and uterus back into a normal position. Vandeplassche[353] has reported that more than 80% of term torsions can be corrected in this manner. Options for management of a preterm uterine torsion are rolling the mare, flank laparotomy, or a ventral midline celiotomy.

The anesthetized mare may be rolled in an attempt to rotate the body of the mare around the stationary gravid uterus.[354] Placement of the mare in lateral recumbency on the side of the torsion is essential. The aim of the procedure is to roll the mare such that the pelvis literally catches up with the displaced uterus. Correction by rolling the mare is controversial.[325,337,344,353] Citations in the literature report on a limited number of cases.[338,345,354] Concerns with this approach include unsuccessful attempts to correct the torsion prolong its adverse effects; misdiagnosis of the direction of the torsion means that rolling the mare may make the condition worse; inability to evaluate the condition of the uterus; and the potential for creating a displaced colon.[325] In addition, the risk of placental detachment and uterine rupture is reportedto be higher.[337,338,345] Another concern is that if general anesthesia is induced under less than ideal conditions, then maternal hypoxia may cause fatal complications in the already compromised fetus.[355]

In the standing flank approach, one makes a grid incision on the same side as the direction of the torsion.[344] One corrects the torsion by placing the forearm under the uterus and then rocking the uterus and contents back and forth to gain momentum. A combination of lifting and rotating movements generally results in easy correction of the torsion. The presence of a live fetus greatly facilitates the detorsion manipulations. One may experience more difficulty in mares that are close to term. In these cases an incision in the opposite flank permits a second surgeon to assist by gently pulling across the top of the uterus as it is elevated from below.[348] If the fetus is dead, the mare should abort naturally once the uterine torsion has been corrected, thereby avoiding hysterotomy and any associated complications.[217,325,326] However, one should monitor the mare closely, and obstetric assistance must be available to correct any malposition or malposture. One should operate on intractable mares under general anesthesia.[338,344] A ventral midline celiotomy also is indicated when one is concerned about significant uterine compromise or if one suspects another problem coexisting in the abdomen.[325]

The prognosis for mares with uterine torsion depends on the degree of vascular compromise. Severity and duration of the condition affect placental circulation and subsequent fetal viability.[325] In chronic cases in which uterine compromise is significant, performing an ovariohysterectomy to salvage the mare for nonbreeding purposes is feasible.[343,347] In the author's experience, if the fetus is alive and the uterine wall is 1099
not severely congested and edematous, then the prognosis for survival of the mare and for the birth of a live 1100
foal at term is good.[325,341] Progestin supplementation for 3 to 5 days after the manipulations involved in correcting a uterine torsion may be indicated to ensure myometrial quiescence and thus maintenance of the

placental attachment.[85] Although supplementation after a uterine torsion would be in the last 2 to 3 months of gestation, some authors report mares retaining a nonviable (died at 3 to 5 months of gestation) fetus while being administered progestins.[189] Thus if one administers progestin supplementation to a mare after correction of a uterine torsion, monitoring of fetal viability at regular intervals is prudent.[325] Continuation of the supplementation once the mare has been discharged from the hospital has little merit.

16.8.7.4 VAGINAL HEMORRHAGE

Visible blood on the tail hairs and hindlimbs of a pregnant mare warrants a careful vaginal examination. Three barriers protect the fetus: vulvar lips, vestibular sphincter, and cervix. Because one will enter two of these barriers when performing a vaginal speculum examination, one must ensure stringent hygiene. Often one can see blood clots in the vestibule on parting the vulvar lips. One should cover a sterile speculum with sterile lubricant and then gently insert it into the vagina. Often no blood is visible in the cranial vagina. If the cervix is closed, pale, and covered with tenacious mucus, then the blood likely is not associated with fetoplacental unit. Although the blood could be associated with cystitis or urolithiasis, in most cases the source of the hemorrhage is varicose vessels in the remnants of the hymen at the level of the vestibular sphincter. To miss these on insertion of the speculum is not unusual. Thus one should pay particular attention to this area while withdrawing the speculum. In some cases, introduction of a fiberscope permits easier visualization of the distended vessels. One can ligate, or in some instances cauterize, the varicosities.

16.8.8 Fescue Toxicity and Agalactia

A wide range of reproductive problems (thickened placenta, abortion, prolonged gestation, dystocia, dead or weak foals, agalactia) have been attributed to the effects of the fungal endophyte *Acremonium coenophialum*, now known as *Neothyphodium coenophialum*.[356–358] The endophyte produces a dopaminergic, vasoactive, ergopeptine alkaloid (ergovaline).[356] This alkaloid disrupts the fetoplacental production of progestagens, but the precise mechanism has not been established.[91,94,359,360] Umbilical vein progestagen levels suggest that the disruption isnot at the level of placental steroidogenesis, a remarkable observation when the fetal membranes are so edematous. Premature chorioallantoic separation and the failure of the membrane to rupture (“red bag”) are attributable to the edematous splanchnic mesoderm.[356] ACTH, thyroxine, triiodothyronine, progestagen, and cortisol concentrations are lower in foals born to endophyte-exposed mares, suggesting that the effects are actually at the level of the fetal hypothalamo-pituitary axis, thyroid, and adrenal cortex.[94,361] This is likely to be the basis for the prolonged gestation and fetal dysmaturity that are associated with fescue toxicosis.[94,359] The ergovaline also inhibits prolactin secretion in affected mares by acting as a dopamine agonist at the maternal pituitary level.[123,124,360] Prolactin secretion can be inhibited experimentally by administration of dopamine agonists such as bromo cryptine. Not only does such prolactin-inhibiting treatment of pregnant mares result in agalactia, but it also mimics the other symptoms of fescue toxicosis (thickened placenta, prolonged gestation, and dystocia).[125] Ryan PL, Bennett-Wimbash K, Vaala WE, et al.[237] have demonstrated that an effect of fescue toxicosis in pregnant mares is a lowering of the circulating relaxin levels. Clinical observations suggest that a one-time injection with fluphenazine improved pregnancy outcome by reducing the adverse effects of fescue toxicosis concomitant with a stabilization of plasma relaxin concentrations. These data support the hypothesis that systemic relaxin may be a useful biochemical means of monitoring placental function and treatment efficacy in the mare.

Because late pregnant mares are so susceptible to the toxic effects of ergopeptine alkaloids, they should not be permitted to graze endophyte-infected tall fescue pasture or hay derived from such pasture. Short-term exposure by mares at 300 days of gestation results in a significant decline in prolactin and total progestagen concentrations within 48 hours. Fortunately, removal of pregnant mares (300 days of gestation) from infected pasture results in a significant increase in prolactin and progestagen levels within 3 days and prevents the development of the typical symptoms associated with fescue toxicosis.[94,359] Even when alternate feed sources are limited, one should make every attempt to remove pregnant mares from endophyte-infected fescue by 30 to 60 days before the expected foaling date. When this is not possible, prophylactic administration of the dopamine receptor antagonist, domperidone (Equidone) can prevent the development of fescue toxicosis.[123–125,357,362–365]

16.8.9 Induction of Parturition

Induction of parturition may be indicated as a clinical management procedure for some high-risk pregnancies including mares with hydrops, ruptured prepubic tendon, or ventral herniation. These mares often require assistance with the delivery because the stage II abdominal press will be compromised.[325] This author does not 1100
believe that induction should be practiced for convenience alone.[366,367] One should advise owners that 1101
complications such as dystocia, premature placental separation, fetal hypoxia, and dysmaturity are common sequelae of the induction procedure.[368–370] The aim of a controlled foaling is not only to deliver a viable fetus but also to prevent any injury to the mare that may compromise future fertility.[325]

Induced foalings sometimes are indicated to ensure that optimal veterinary assistance is available when complications are expected and to optimize resuscitation attempts when a compromised fetus has been monitored in utero. When one detects fetal stress in a high-risk pregnancy, the clinician is faced with the dilemma of inducing delivery and attempting supportive care in a neonatal intensive unit or leaving the compromised fetus in utero. One should inform owners that delivery is indicated only if the probability of extrauterine survival exceeds that for continued maternal support. Experience suggests that an abnormal uterine environment often is more successful at maintaining the life of a fetal foal than a neonatal intensive care unit.[316] A fetus that has been exposed to an adverse uterine environment for some time may be more tolerant of premature delivery.[149] Many clinicians administer a dose of corticosteroids to the mare if premature delivery appears to be unavoidable. Corticosteroids may stimulate surfactant production and promote accelerated maturation of the fetal lungs.

The normal physiologic processes in the prepartum mare and fetus have been discussed in a previous section. Final maturation of the fetus results in increased ACTH release from the pituitary gland and subsequent stimulation of the fetal adrenal cortex.[87,90,91] Not until the maturing adrenal gland attains 17α-hydroxylase capacity are the high levels of pregnenolone metabolized into fetal cortisol.[93] These vital changes occur in the last24 to 48 hours before birth, and thus the equine fetus is at a substantially increased risk of dysmaturity/prematurity if one does not plan the induction carefully.[371] Planning traditionally has involved confirmation of gestation length, monitoring mammary development and milk/colostrum production, and ultimately evaluation of the amount of cervical softening.[372] The fetus usually is in dorsopubic position with neck and limbs flexed before induction. The incidence of posterior and transverse presentationsis rare, but detection of these abnormalities by palpation per rectum before induction would be reason to reevaluate the induction plans. Delivery by cesarean section maybe a more prudent course of action, especially with transverse presentations.

Gestation length is notoriously unpredictable in mares.[373,374] Although the frequently recommended minimum gestation length for successful induction is 330 days, one must remember that many mares carry a foal past 340 days and occasionally to 360 days and beyond.[3,372,374,375] In a retrospective study of Standardbred mares the mean duration of gestation was 343.3 days and was significantly greater for colt fetuses (344.4 days) than for filly fetuses (342.2 days). Sire has been associated with duration of gestation; gestation after mating with certain sires was consistently less than 340 days in duration, whereas gestation after mating with other sires was consistently more than 350 days.[376] Mares tend to carry foals longer if they are due to foal early in the season (shorter day length), whereas gestation length may be shorter if the foal is not due until longer days have arrived.[374,376–378] Placentitis and other pathologic conditions of the placenta often are associated with precocious mammary gland development and premature changes in mammary secretion electrolyte concentrations. Milk electrolyte changes are unreliable for assessing fetal readiness for birth in abnormal pregnancies (e.g., placentitis, impending twin abortion). In these cases, mammary secretion calcium concentrations may be elevated (>10 mmol/L; >400 ppm; >40 mg/dl) before day 310 of gestation.[97]

Although mammary development is a useful sign of approaching parturition in normal mares, monitoring changes in mammary secretion electrolyte concentrations is the most reliable guide to imminent parturition.[379–383] An inversion in the sodium-to-potassium ratio, followed by a rapid rise in calcium concentrations in the last 24to 48 hours has been correlated with fetal maturity. Exact values may vary with the type of chemistry analyzer used by the diagnostic laboratory. In a normal term pregnancy the combined mammary secretion levels of calcium(>40 mg/dl), potassium (>30 mEq/ml), and sodium (<30 mEq/ml) indicate fetal maturity.[381] A concentration of 10 mmol/L (40 mg/dl; 400 ppm) calcium in mammary secretions is a reliable indicator of fetal readiness for birth.[373,379,381,383,384] Several stallside tests are available that can measure Ca^{2+} concentration in mammary secretions based on a colorimetric change of pads on a test strip. Water hardness kits are also useful for determining the concentration of calcium in mammary secretions.[371,384–388] These kits involve titration of a diluted sample until an indicator dye changes color, and although they are more labor intensive than the test strips, they are reported to provide a more reliable guide for predicting the onset of parturition within the next 24 hours.[388] However, one must ensure that the water hardness kit is only measuring calcium levels if one is using it to decide when to induce parturition safely. Many kits merely test for divalent cations, which includes magnesium and calcium.[373] Because magnesium levels peak earlier than calcium, one may obtain misleading information about fetal maturity.[383,384] If the intent is merely to predict the onset of spontaneous parturition, then the type of test is not as critical.[373]

A recent publication has questioned the interpretation of $CaCO_3$ test kit data that has formed the basis of 1101
recommendations that 200 or 250 ppm $CaCO_3$ be used as the benchmark for readiness for birth.[373,388,389] 1102
Paccamonti[373] contends that because calcium in milk is not in the form of $CaCO_3$, any test that measures $CaCO_3$ levels in solution must be adjusted to account for this fact. Because the molecular weight of $CaCO_3$ is 100 and that of calcium is only 40, the conversion factor is 2.5 (i.e., divide the $CaCO_3$ parts per million by 2.5 to obtain calcium parts per million). Furthermore, because mammary secretions usually need to be diluted before a water hardness test can be used to measure calcium, Paccamonti recommends that 1 ml of secretion be diluted in 4 ml of distilled water. Thus one should correct the final reading by a factor of 5.[373] The division by 2.5 to convert $CaCO_3$ to calcium and the multiplication by 5 to correct for the dilution means that the test result need only be doubled to provide an accurate level of parts per million of calcium. Using this logic, Paccamonti contends that the reports using 200 to 250 ppm $CaCO_3$ as an indicationof readiness for birth actually are using

calcium values of only 80 to 100 ppm.[373,388,389] However, if these values are corrected for the reported test dilution (1:6) factor, then the $CaCO_3$ level being reported would have been 1400 to 1750 ppm (560 to 700 ppm calcium; 14 to 17.5 mmol/L). These corrected values are thus in excess of the 400 ppm (10 mmol/L) calcium concentrations reported by others.[373,379–381,383,384] Obviously, keeping these calculations in mind is important, because water hardness kits may vary, and technicians may use different dilutions. Inappropriate application of the math could lead to an erroneous conclusion about fetal maturity and subsequent induction of a premature foal.[373]

In general, mammary secretion calcium concentrations are more reliable for predicting when a mare is unlikely to foal spontaneously rather than for determiningwhen she is likely to foal.[373,384] Ley et al. used a water hardness kit and reported that $CaCO_3$ levels greater than 200 ppm (see the preceding discussion) indicated a54% probability of spontaneous foaling within 24 hours, 84% probability of spontaneous foaling within 2 days, and 97% probability of spontaneous foaling within 3 days. A small percentage of mares foaled within 24 hours despite a $CaCO_3$ level less than 200 ppm.[388,389] However, using Paccamonti's logic, this equates to a corrected value of less than 560 ppm Ca^{2+}.[373] Because a value of 400 ppm Ca^{2+} indicates readines for birth, that some of these mares foaled is not surprising. Although the fetus initiates parturition, the mare appears to be able to regulate the actual timing of delivery.[367] Thus any untoward changes in the environment of the mare may cause her to postpone the delivery and thus create disagreement with predictions based on mammary secretion electrolyte concentrations. Calcium levels can change rapidly during a single day. Thus testing secretions morning and evening may be useful. If one performs only a single test, checking the calcium levels late in the day is preferable.[373] Generally, the more rapid the rise in milk calcium levels, the more imminent is parturition. Primiparous mares can be especially difficult to monitor because no change in mammary secretion electrolyte composition may be detectable until immediately before foaling.[371]

The presence of cervical softening traditionally has been suggested as a prerequisite for optimal induction of parturition in the mare, and in a recent study mares with a relaxed cervix before induction had a more rapid delivery.[334,372] This study found that foals delivered from mares with a preinduction relaxed cervix stood and nursed sooner and had fewer signs of intrapartum asphyxia (hypercapnia, maladjustment) than foals delivered from mares with a nondilated cervix. Those mares that developed parturient complications (premature placental separation, dystocia) all had a closed cervix before induction.[334] The status of the cervix is controversial because earlier reports suggest that inductions may proceed successfully even though the cervix is tightly closed and covered with mucus.[368] A recent innovation has been the intracervical administration of PGE_2 (2.5 mg) before induction, but no difference was apparent in the mean interval from initial oxytocin treatment to rupture of the chorioallantois or to the delivery of the foal.[333] However, the affect on foal viability was positive in that foals delivered from PGE_2-treated mares suckled sooner. The application of PGE_2 intracervically may have some merit when terminating a pathologic pregnancy (e.g., hydrops) in which the induction is known to be premature and is aimed at salvaging the breeding prospects of the mare. Although no correlation exists between myometrial strip (in vitro) response to oxytocin treatment and gestational age, in the author's experience, premature induction with oxytocin can take much longer (1 to 2 hours) than an induction in mares at term.[148,390] This is consistent with the belief that a critical sequence of hormonal changes is required before fetal expulsion can occur.[148] Because the aborted fetus generally is alive and gasping for air, having some euthanasia solution ready to destroy the nonviable neonate humanely is advisable.

Several experimental protocols have been reported for induction of parturition in the term mare, including glucocorticoids,[370,391,392] prostaglandins,[368,370,381,393–398] and oxytocin.[*] High and repeated doses are required for glucocorticoid induction, because unlike with ruminants, this regimen has limited efficacy in the mare. Likewise, prostaglandin induction is not efficient in the mare. The synthetic products (fenprostalene, fluprostenol, and prostalene) are more effective than natural prostaglandin, but results can vary.[368,370,381,393–398] 1102
1103 Oxytocin is the preferred drug for induction of parturition in the mare. A wide range of protocols have been suggested over the years, including a bolus dose (20 to 75 units), low doses(2.5 to 20 units) repeated every 15 minutes to effect, and a slow intravenous drip of 60 to 120 units total(1.0 unit/min).[*] Recent work suggests that the choice of oxytocin regimen is less important for foal viability than appropriate case selection and adherence to criteria for induction.[334,371] A low-dose protocol has been recommended because it appears to work only in those mares that have a mature fetus. Mares were diagnosed as being ready for birth by mammary secretion calcium strip test measurements. A single intravenous injectionof 2.5 IU oxytocin was given between 5 P.M. and 7 P.M. and resulted in the delivery of a normal foal within120 minutes in 95% of mares. Twenty-four of 38 (63%) treated mares foaled in response to the first oxytocin injection. Another 9 of 38 (24%) foaled the following evening in response to the second injection, and 3 of38 (8%) foaled in response to the third treatment. The conclusion was that the major advantage of injecting a daily low dose of oxytocin appears to be that such a low dose only induces delivery in mares that are carrying a mature fetus and that are ready to foal. This low-dose, early-evening oxytocin protocol has been proposed to be used as a reliable method to induce parturition or to predict that the mare would not foal that night if parturition did not occur within 2 hours of treatment.[402] However, even this promising protocol has limitations because it is still possible occasionally to induce a mare to deliver a premature foal.

Because one performs most inductions based on an expectation of complications, the clinician should be well prepared before administration of the induction agent (low-dose oxytocin).[373] Even if the induction is not being performed by an intravenous drip, insertion of an indwelling catheter is recommended. The catheter facilitates rapid induction of general anesthesia if obstetric difficulties ensue. One should place a fully stocked obstetric kit and ample volumes of lubricant outside the stall. One should anticipate neonatal resuscitation efforts and should have appropriate supplies (e.g., oxygen delivery system) readily available. Premature separation of the placenta is a common complication of induced births. The clinician should rupture the exposed chorioallantois immediately and then assist with fetal delivery along with the expulsive efforts of the mare. Overzealous traction at this time may cause a laceration of the cervix if it has not yet dilated fully. If necessary, one can place an oxygen tube in the nostril of the foal during the minute or two that may be required to complete the assisted delivery.

16.8.10 Obstetrics

16.8.10.1 MANAGEMENT OF THE PREGNANT MARE

A series of publications that discuss the effects of nutrition on various aspects of equine reproduction have been published recently.[404–407] Regular exercise and routine hoof maintenance are important for broodmares. A regular anthelmintic program is essential to ensure the well-being of the mare and also reduces the exposure of the foal to parasite eggs in the feces of the mare and the transmammary transfer of *Strongyloides*

westeri larvae. Pregnant mares should be current for all vaccinations that are recommended for that particular geographic location.[408,409] In North America, advising owners about the importance of a regular vaccination program for equine herpesvirus is especially important. Owners and or farm managers should be aware of the need to isolate pregnant mares from transient horses to reduce the risk of infectious disease, especially respiratory viral infections. A tetanus booster may be indicated a month before foaling. Another recommendation is that the mare be transferred to the final foaling environment at least a month before the due date. Foals are born essentially agammaglobulinemic, and the neonate depends on passive transfer of colostral immunoglobulins to provide initial protection from environmental pathogens. If a vulvoplasty (Caslick) has been performed, one should make plans to open this approximately a week earlier than the expected foaling date. If the mare has a history of a previous hemolytic foal (neonatal isoerythrolysis), then one should make plans to prevent the neonate from suckling the mare until all the colostrum has been stripped out (see Chapter 19).

Those persons responsible for monitoring the foaling process should understand that mammary development, followed by distention and waxing of the teats, and then relaxation of the perineal area indicate approaching parturition in the mare. The use of mammary secretion electrolyte concentrations to predict foaling has been discussed in a previous section. Electronic monitoring systems are also available that can signal the start of parturition. One should counsel inexperienced personnel about normal foaling events and how to recognize when professional assistance is required. Inappropriate intervention by ill-informed individuals can jeopardize the life of the foal and potentially cause life-threatening complications in the mare. Separation of the fetal membranes deprives the fetus of oxygen, and this is the critical factor one must consider when assessing an obstetric case that involves a live foal. Although most references suggest that fetal survival rates are low if the foal is not delivered within 30 to 40 minutes of chorioallantoic rupture, one author reports having delivered live foals by cesarean section up to 90 minutes later.[410] These are mares that were presented 1103
promptly to the veterinary hospital and that had minimal, if any, vaginal intervention at the farm. The limited 1104
vaginal intervention likely is less disruptive to the placental attachment, and thus these foals are not deprived of their oxygen supply. Keeping the mare on her feet, and walking if necessary, may help to reduce straining while professional assistance is sought.

16.8.10.2 NORMAL PARTURITION

16.8.10.2.1 Terminology

The terms *presentation, position*, and *posture* describe the disposition of the fetus as it enters the vaginal canal. Often a fetus is described as having been malpresentedor malpositioned when the only anomaly present is postural, the most common cause of dystocia in the mare.[411] In an attempt to avoid confusion, Vandeplassche introduced the all-encompassing term *fetal maldisposition* to describe the combination of presentational, positional, and postural abnormalities that can contribute to a dystocia.[353] Presentation describes the aspect of the fetus that enters the vaginal canal first and also the orientation of the fetal spinal axis to that of the mare (anterior or posterior longitudinal; ventro- or dorsotransverse). More recently the tendency has been toward using the terms *cranial* and *caudal presentation*. Position describes the relationship of the fetal dorsum (longitudinal) or head (transverse) to the quadrants of the pelvis of the mare. The normal position for delivery is dorsosacral. A fetus that is still on its side would be right or left dorsoilial, and a fetus that is upside down would be dorsopubic. The terms *right* and *left cephaloilial* refer to the position of the fetal head relative to the pelvic walls of the mare and imply that a transverse

presentation is present. Posture is purely fetal and describes the relationship of the extremities (head, neck, limbs) to the body of the foal.[159,411]

16.8.10.2.2

Fetal Kinetics

Fetal mobility has been discussed concerning umbilical cord torsion and abortion. Fetal rotation within the amniotic cavity and amniotic sac rotation within the allantoic cavity result in the characteristic twisting of the umbilical cord.[286,290] Some highly efficient mechanism ultimately guides most equine fetuses into a cranial presentation.[4] Ultrasonographic studies have notedthe percentage of anterior, posterior, and transverse presentations at 5 to 6 months to be 52%, 29%, and 19%, respectively, but between 7 and 11 months the fetal presentation becomes predominately anterior.[286,287,289,290,296] Vandeplassche reported the incidence of anterior, posterior, and transverse presentations in the normal parturient mare population to be 98.9%, 1.0%, and 0.1%, respectively.[353,412] Ginther[286,289] and Ginther and Griffin[288] observed that muscular contractions close the lumen of both uterine horns between 5 and 7 months, and thus the allantoic fluid along with the fetus is confined to the uterine body. During this time, the fetus positions itself so that its head end points toward the cervix of the mare (cranial presentation).[287,288,296] The neurologic signals within the fetal inner ear have been proposed to respond to the slope of the ventral uterine wall and to guide the fetus to lie with its head elevated toward the cervix.[289] In most cases the noncord horn remains closed, whereas the cord horn gradually permits the entry of the hindlimbs between 7 and 9 months. The limbs can enter the horn only when the fetus is in dorsal recumbency because the angle is so acute between the horn and body by this stage of gestation. Thereafter the hindlimbs remain enclosed within the cord horn and the hooves extend to the horn tip by the 10th month.[286–289] Thus the selective closing and opening of the uterine horns, with subsequent trapping of the hindlimbs, is believed to be a key feature of the mechanism that ultimately directs fetal orientation into cranial presentation.[287,289] Entrapment of the hindlimbs within the uterine horn generally means that the caudal portion of the anteriorly presented fetus is lying in a dorsopubic, and occasionally dorsoilial, position.[289] Ginther's ultrasonographic investigations have substantiated the classic radiographic study that demonstrated that the full-term equine fetus initially is lying in a dorsopubic position with the head, neck, and forelimbs flexed.[413]

In early pregnancy the mesometrial attachments suspend the uterine horns so that they point cranially and dorsally, but by late gestation the horn containing the hindlimbs comes to rest on the dorsal surface of the uterine body, with the tip of the horn directed back toward the cervix.[4,287] The hooves and horn tip may be pushed so far caudally that they actually come to lie over the fetal head, meaning that when one performs a per rectum evaluation of a mare in late gestation, the fetal hooves that are palpable may be attached to the hindlimbs. In some mares the vigorous pistonlike thrusts of the hindlimbs in association with elevation of the fetal rump may push the hooves past the cervix into the rectogenital pouch.[4,287,289] This observation may explain the acute colic episodes that previously have been attributed to uterine dorsoretroflexion.[326] Although the caudal aspect of the fetus is associated intimately with the uterine wall, the cranial portion has room to rotate within the uterine body itself. Ultrasonographic studies on mares closeto term (>330 days of gestation) have shown that the cranial half of the fetus was in dorsopubic position approximately 60% of the time and in dorsoilial position about 40% of the time. The forelimbs and head usually were flexed (about 80%), but in the remainder the head or limbs were extended.[289] Postural changes are common, and thus palpation per rectum before the onset of first stage labor is not a good predictor of 1104

impending dystocia.[289,411] However, detection of a posterior or transverse presentation at this late stage is cause for concern, and one should make appropriate plans to manage the impending delivery. 1105

16.8.10.2.3
Stages of Parturition

Behavioral changes that characterize the first stage of parturition include the mare looking at her flank, frequently lying down and getting up, stretching as if to urinate, and passing small amounts of feces. Patchy sweating may develop, and some mares leak colostrum.[159,411] The restless behavior is similar to that of mild colic and is associated with the development of coordinated uterine contractions that increase uterine pressure and push the chorioallantoic sac (in the region of the cervical star) into the gradually dilating cervix. The increasing uterine tone during stage I of parturition has been proposed to stimulate the fetus to extend its head and forelimbs up into the dilating pelvic canal.[4] Once the head and forelimbs are extended fully, they are unlikely to return to a flexed posture unless the foal reacts to manual intervention on the part of a foaling attendant. However, the neck or a forelimb possibly may develop a malposture if not correctly aligned when the mare begins an expulsive effort. Passage of the urinelike allantoic fluid (waters breaking) concludes the first stage of labor. Rupture of the chorioallantois and passage of the allantoic fluid does not occur until the fetlocks, or sometimes the knees, are at the level of the external cervical opening. If the chorioallantois does not rupture, then further separation from the endometrium can result in a “red bag” delivery with the velvety, red membrane appearing at the vulvar lips. In a normal delivery, the chorioallantois is thought to remain attached to the endometrium until after the foal is delivered.[411]

Failure of rupture of the chorioallantois is a common complication of induced parturition.[334] If this happens, then continued separation from the endometrium will compromise transplacental oxygen exchange, and the likelihood of fetal hypoxia is high. Thus premature separation of the placenta is an emergency situation, and one should instruct foaling attendants to break the membrane and to provide gentle traction in unison with the expulsive efforts of the mare. Although the foal should be delivered as quickly as possible, injudicious traction at this time may cause a laceration in an incompletely dilated cervix.[411] Applying traction only with the expulsive efforts of the mare reduces the likelihood of creating cervical trauma.

As parturition progresses, passage of the fetus into the pelvic inlet initiates a reflex release of oxytocin from the posterior pituitary (Ferguson's reflex), thereby enhancing uterine contractility.[159] Stage II is characterized by strong abdominal contractions that provide the expulsive force necessary to expel the fetus. Most mares assume lateral recumbency once active straining commences. Many mares get up once or twice during second-stage labor in what is believed to be a further attempt to position the fetus correctly.[411] One can expect the translucent fluid-filled amnion to appear at the vulvar lips within5 minutes of rupture of the chorioallantois.[414] Any delay in the stage II expulsion process increases the likelihood of fetal asphyxia or neonatal problems associated with hypoxia because of placental separation. At least one hoof should be visible within the amniotic sac, and the other should be located a couple of inches behind it. If everything is progressing normally, the soles of the hooves should face down toward the hocks of the mare, and the head of the foal should be resting between the carpi.[411]

By the time the nose has reached the vulva, the cranial half of the torso should have rotated from a dorsopubic to a dorsoilial position.[4] The mare probably assists the fetus to reposition itself by the characteristic side-to-side rolling each time she becomes recumbent.[411] Some dystocias involving fetal

malposition and/or malposture likely are caused by the failure of a compromised fetus to participate actively in the foaling process. Many authors have suggested less vigorous or absent fetal righting reflexes early in the parturient process as a cause of fetal maldisposition.[159,339,413] The observation that ventral deviation of the head and neck is more likely to be present if the fetus is in dorsoilial position than in dorsosacral position further substantiates the hypothesis that the fetal righting reflexes are compromised early in these cases.[339]

The second stage of labor in the mare is rapid, with the most forceful contractions occurring as the chest passes through the pelvic cavity. Most foals are delivered within 20 to 30 minutes after the chorioallantoic membrane ruptures. Primiparous dams generally require longer to expel the fetus than do multiparous dams.[159,414] The amniotic sac usually ruptures during these expulsive efforts.[411] However, the equine amniotic sac is not attached to the chorioallantois as is the case with a ruminant placenta, and the foal sometimes may be delivered with a portion of the sac wrapped around its head.[414] One should instruct foaling attendants to free the head of the foal promptly from the amniotic sac to prevent suffocation. Active straining ceases once the hips of the foal are delivered, and the mare will rest in lateral recumbency.[411] An active foal will extract the hindlimbs from the vagina as it struggles to stand. The third stage of parturition involves expulsion of the fetal membranes, and this typically takes between 30 minutes and 3 hours.[159] One should advise owners to seek veterinary assistance if passage of the membranes is delayed, because life-threatening toxic metritis and laminitis are common sequelae of membrane retention.[411] 1105

1106

16.8.10.3 CAUSES OF DYSTOCIA

The incidence of dystocia in the general horse population varies among breeds: Thoroughbreds (4%), Shetland Ponies (8%), and Draft breeds (10%).[353] Dystocia is one of the few true emergencies in equine practice, where literally a matter of minutes can determine a successful outcome—birth of a live foal.[411] Perinatal asphyxia associated with dystocia is a major cause of equine reproductive loss.[223] The long fetal extremities (limbs, neck) predispose the mare to foaling problems.[159,353,411] Alert, informed foaling attendants are essential to ensure early recognition of abnormalities. Attendants should suspect that the mare is experiencing obstetric problems if the first or second stage of parturition is prolonged or not progressive.[411] Signs that a mare may be in dystocia include failure of any fetal parts or of the amniotic membrane to appear at the vulvar lips for a prolonged period of time after rupture of the chorioallantois, appearance of only one hoof at the vulva, hooves upside down at vulva, hooves and nose in abnormal relationship, nose but not hooves at vulva.[414] The most common impediments to delivery are malpostures of the fetal extremities (head and neck; limbs).[339] An experienced foaling attendant may be able to correct minor problems and facilitate a successful delivery. However, inappropriate intervention can have potentially fatal consequences for the mare. Furthermore, obstetric manipulations easily can damage the uterus and cervix to the extent that the reproductive future of the mare is jeopardized.[411]

16.8.10.4 MANAGEMENT OF DYSTOCIA

When attending to a mare in dystocia, the veterinarian should make a rapid assessment of the general physical condition of the mare, noting in particular mucous membrane color and refill time (hemorrhage, dehydration, shock).[411] A mare that is aborting in late gestationmay experience a dystocia because the dead fetus cannot participate in the delivery process. A malodorous discharge strongly suggests the presence of an

emphysematous fetus. One should inspect the perineal area for the presence and nature of any vulvar discharge and the presence of fetal membranes and to identify any fetal extremities. Excessive hemorrhage and vulvar swelling may indicate that nonprofessional intervention has caused trauma to reproductive tract. Occasionally, a mare has a rectal prolapse, an everted bladder, or intestinal loops protruding from the vulvar lips. The intestines may be of fetal origin if incomplete closure of the ventral abdomen has occurred, but a ruptured vagina is more likely. In the later scenario, the foot of the foal may have ruptured the floor of the cranial vagina, but one should not discount injudicious manipulations by an inexperienced attendant. If a rectal prolapse or the urinary bladder is present, then one should administer an epidural anesthetic to prevent further straining. Alternately, one may anesthetize the mare to facilitate hoisting the hindquarters.[411] The advantage of this approach is stopping the straining immediately, which is especially important if the prolapse involves an intussuscepted colon (type IV).[415,416] In these cases a palpable trench may extend several feet into the rectum, and avulsion of the mesentery can be a fatal complication that is not readily amenable to surgical correction.

This author considers stocks to be contraindicated when examining a foaling mare and prefers to perform the initial examination on a standing mare with no more restraint than a twitch or lip chain if her demeanor permits this to be performed safely. The behavior of a mare in stage II labor is unpredictable and may be violent. One must ensure that the examination area is clean and has good footing. Space should be ample for the mare handler, obstetrician, and assistants to move to safety if necessary. Although most veterinary tranquilizers readily cross the placenta and can compromise the fetus, adequate restraint is essential for the safety of all concerned.[417] Sedation with tranquilizers may be necessary for some uncooperative mares, and in extremely intractable cases, anesthetization of the mare with a short-acting combination may be preferable. In these cases, a hoist should be available because manipulating the foal when the mare is in lateral recumbency can be difficult. Although not essential, an initial rectal examination can rule out the presence of a term uterine torsion, determine the condition of the uterine wall (tears, spasm), and may provide useful information regarding the disposition of the fetus. Before any vaginal examination, one should wrap the tail of the mare and thoroughly clean the perineal area. The clinician should scrub the arms and hands with disinfectant soap.[411] In a hospital environment, the author also wears sterile rubber obstetric sleeves. Cleanliness and lubrication are the cornerstones of obstetrics.

Friction associated with vaginal manipulations easily traumatizes the vagina and cervix of the mare. Once the mucous membrane has been abraded, adhesions and fibrosis are likely to follow. Thus copious amounts of lubricant are vital to ensure that the soft tissues of the genital tract are not traumatized so as to preserve the future fertility of the mare.[418] Lubricants include methylcellulose, polyethylene polymer, white petrolatum combined with 10% boric acid, and mineral oil. Water-soluble lubricants are generally not as desirable because they rapidly lose their lubricating abilities in the presence of fluids.[159] If a large volume of lubricant is to be pumped around the fetus, then a preceding investigation of the possibility of a uterine laceration is essential. In a referral situation, the author routinely performs an abdominocentesis. Serosanguinous to 1106
sanguinous fluid that contains elevated total protein levels and an increased white blood cell count is highly 1107
suggestive of a uterine rupture.[350] If no likelihood of a uterine tear is apparent, the author prefers to mix a polyethylene polymer powder with warm water and then to use a clean stomach tube and pumpto instill large volumes of lubricant gently into the uterine lumen.[418] The author repeats this procedure as oftenas necessary to keep the fetus and reproductive tract coated with lubricant.

One should explore the vagina, cervix, and accessible parts of the uterus carefully to ascertain the source of any hemorrhage. One should note any lacerations and discuss their presence with owners or the attending personnel before attempting any veterinary manipulations. Occasionally, the cause of the dystocia is a pelvic

deformity (e.g., callus). One must determine the degree of cervical dilation.[411] If the mare has been in labor for some time, the uterus possibly is relatively dry and tightly contracted around the fetus, which makes intrauterine manipulations much more difficult, especially because safely repelling the fetus back into the uterus becomes difficult. If the uterus is contracted, warm lubricant tends to induce some uterine relaxation, and the volume expansion creates some additional space in which to perform manipulations.[337,418] One can control myometrial contractions (uterine spasm) by tocolytic drugs (isoxsuprine, clenbuterol) if they are available for veterinary use.[353] Although fetopelvic disproportion is uncommon in the mare, it can be a factor in some equine dystocias.[38,39,41,411] One should note the disposition of the fetus and determine fetal viability. One should exercise care because active fetal response to manipulations easily can complicate an initially simple dystocia. Placement of a rope snare behind the ears and into the mouth of the foal ensures that the clinician always has control of the head and facilitates easy correction of a potentially life-threatening development such as lateral deviation of the head and neck if the fetus pulls away from the clinician's manipulations.[411] If one places the snare around the mandible, application of only gentle traction to guide the fetal head through the vaginal canal is essential. Excessive force may cause a fracture of the mandible. When obvious fetal movement is absent, one may initiate digital withdrawal in response to pinching of the coronary band. Slight digital pressure over the eyelid onto the eyeball may arouse a response, as may stimulation of the tongue (swallowing). If one can reach the thorax, a fetal heart beat is a definitive sign of life. In posteriorly presented cases the digital and anal reflexes are useful as indicators of fetal viability. Occasionally, reaching the umbilical cord may be possible.[159]

The clinician should inform the owner of the various options, costs, and prognosis once the current status of the foal is known, and the cause of the dystocia has been determined. Ensuring that the owner is aware of the potential complications that may arise is especially important, because postpartum medical care can become expensive. If delivery of a live foal is anticipated, the clinician should consider the potential for fetal cardiovascular compromise before administering any tranquilizers to the mare.[411] Light sedation of the mare with acetylpromazine (2 to 3 mg/100 kg intravenously) has minimal effect on the foal and may be useful in some cases. Xylazine is preferable to detomidine if the fetus is viable because its depressant effects are of much shorter duration.[419] However, one should use neither xylazine nor detomidine on its own to sedate a mare with dystocia because some apparently sedated mares can become hypersensitive over the hindquarters.[419,420] The combination of xylazine and acepromazine provides good sedation in a quiet mare.[417] The author routinely uses a combination of xylazine(0.3 to 0.5 mg/kg intravenously) and butorphanol (0.01 to 0.02 mg/kg intravenously) for standing obstetric procedures if more sedation is required (e.g., fetotomy procedure). This provides good sedation and analgesia, and one may administer additional doses as necessary. The clinician instructs the attendants to keep the lip chain loose and to tighten it only when instructed to doso. This ensures that the lip chain retains its effectiveness when required to divert the attention of the mare.[411] LeBlanc[417] suggests a combination of xylazine (1.1 mg/kg) and morphine (0.1 to 0.2 mg/kg) to sedate mares for fetotomy but cautions that gastrointestinal stasis is a frequent complication. Although one can resolve most dystocias at the farm quickly by brief manipulation and assisted vaginal delivery, the practitioner should consider the alternatives if resolution is likely to take more than 10 to 15 minutes. Prolonged, unproductive vaginal manipulations are contraindicated in equine obstetrics. One should base decisions for the next recourse on the viability of the foal, the clinician's obstetric skills, the availability of equipment and facilities, and certainly the financial constraints imposed by the owner.

An epidural anesthetic does not prevent the myometrial contractions or the abdominal press of the mare, and the time involved in administering an effective epidural anesthetic may make this form of restraint impractical when a live foal is present.[411,419] However, if the foal is dead, epidural anesthesia does reduce

vaginal sensitivity and thus the perception of the mare of vaginal manipulations (Ferguson's reflex). Caudal epidural anesthesia should be used at the clinician's discretion, especially if general anesthesia or referral may become necessary. When an epidural is indicated, the author uses a combination of xylazine (0.17 mg/kg) and lidocaine (2 to 3 ml) diluted in saline, such that the final volume does not exceed 8 to 10 ml in order to reduce the likelihood of hindlimb weakness.[419,421] Excess volume can cause the mare to become ataxic. 1107
Short-term general anesthesia may be indicated when minor postural abnormalities are present and maternal 1108
expulsive efforts make correction difficult.[355] A combination of xylazine (1.1 mg/kg intravenously) followed by ketamine (2.2 mg/kg intravenously) provides a smooth, short-duration (10- to 15-minute) general anesthetic. Addition of the central-acting muscle relaxant guaifenesin (1 L of a solution of 5% guaifenesin in 5% dextrose) can provide an additional 10 to 20 minutes for fetal manipulation.[419] In specialist equine hospitals located close to well-managed broodmare farms, the fetus is often still alive when the mare arrives.[410] Common practice is immediately to anesthetize these mares and maintain them on halothane and oxygen with controlled ventilation. Halothane anesthesia has been shown to compromise umbilical circulation, and thus one should keep the concentration to a minimumif the foal is still alive.[355] Total intravenous anesthesia (the so-called triple drip of ketamine, xylazine, and guaifenesin) may be preferable until the foal has been delivered.[417] One should ventilate the mare with oxygen and administer fluids intravenously as required. Using the hindend elevation technique, one can resolve almost three fourths of such cases by controlled vaginal delivery. However, if the fetus is still alive and has not been delivered within 15 minutes, one must perform an immediate cesarean section, with a 30% foal survival rate possible, provided that the time from rupture of the chorioallantois to presentation at the veterinary hospital has been kept to a minimum.[410,422] In the field, if a hoist is available, one can place hobbles on the hind pasterns and elevate the hindquarters briefly 1 to 2 feet. The combination of a relaxed uterus and the effects of gravity can facilitate fetal repulsion and manipulation. If attempts at mutation are successful, one should lower the mare into lateral recumbency to permit extraction of the foal.[411] Prolonged dorsal recumbency results in compression of the aorta and vena cava and reduction in venous return, cardiac output, and blood pressure.[417] Hindlimb paresis may develop after prolonged hindquarter suspension and can complicate the recovery process. The use of pads to support the hindquarters helps to take some weight off the limbs while the mare is suspended.

Mutation is an obstetric term that describes manipulation of the fetal extremities, together with correction of any positional abnormalities so that assisted vaginal delivery can proceed.[159] Although extra space is available for manipulations when the fetus has been repelled back into the uterus, the clinician should remain cognizant at all times that overzealous obstetric manipulations are a major cause of uterine rupture.[159,337,349,350,423–427] Repulsion of the fetus from the maternal pelvis is contraindicated if the uterus is contracted down around the fetus. In some cases, pumping warm obstetric lubricant around the fetus induces some uterine relaxation. In those countries where they are legal, tocolytic agents are effective in relaxing a contracted uterus. If the fetus is dead, many cases may be amenable to correction by fetotomy provided that the clinician has the appropriate skills and equipment.[428–430] Poor technique and inappropriate cuts often lead to infertility. The alternative is cesarean section.[422]

One must apply traction with careful regard for maternal and fetal well-being. Often traction applied entirely by hand is all that is necessary. Obstetric straps or chains may provide a better grip. This author prefers to apply one loop above the fetlock, with a second loop encircling the pastern. In assisted vaginal deliveries, one should apply traction as an adjunct when the mare is exerting expulsive force and should release the traction when the dam stops straining, thereby permitting rest and recovery. This approach is critical to permit adequate dilation of the caudal reproductive tract.[418] Copious lubrication and slow traction with

continuous monitoring of cervical dilation are especially important to perform a controlled vaginal delivery on an anesthetized mare.[422] Excessive use of force may be associated with fetal fractures (ribs, vertebrae, and limbs) and maternal soft tissue trauma. A maximum of two to three persons (depending on size and strength) should apply traction to the fetus.[418]

16.8.10.4.1 Cranial (Anterior) Presentation

An anteriorly presented fetus in dorsosacral position with head and forelimbs extended should require minimal traction to complete the delivery, assuming that the vaginal canal is well lubricated. By ensuring that slightly more traction is applied to one limb than the other, one can reduce the width of the fetus across the shoulders and deliver most foals successfully. If one is not making progress, then all traction should stop and one must explore the vaginal canal fully.[418] The three likely possibilities for difficulty are elbow lock (incomplete extension of the forelimb), dog-sitting/hurdling posture, and occasionally fetal oversize. Absolute or relative fetopelvic disproportion is uncommon in the mare, even in those cases in which the foal has been carried several weeks past the expected due date. In fact, some cases of prolonged gestation may involve a smaller than normal, dysmature fetus.[159,431] In a referral hospital study, less than 2% of dystocias were attributed to this condition.[339] Of significance, however, is that approximately 30% of referral hospital dystocia cases are in primiparous mares.[339,412,414] Primiparous mares were represented disproportionately in a report on dystocia and neonatal asphyxia from the central Kentucky area.[181,432] Thus although fetopelvic disproportion is not common in the mare, obstetric assistance (traction) is required much more often in primiparous mares.[353,432,433] Dystocia in these mares is complicated further 1108
by a tight vaginovestibular sphincter, which may predispose primiparous mares to lacerations and 1109
rectovaginal tears.[432] If copious lubrication and gentle traction do not help, cesarean section or partial fetotomy are the only alternatives.

Incomplete elbow extension may be uni- or bilateral and should be suspected if the fetal muzzle lies at the same level as the hooves.[418] In this posture the fetal elbows are tucked back under the shoulder joint, causing increased depth and width of the fetus within the maternal pelvic inlet. Correction involves repelling the fetal trunk so that the forelimbs can be extended and thus raise the elbows up over the floor of the pelvic inlet.[337] In a dog-sitting/hurdling posture the fetus has bilateral (dog-sitting posture) or unilateral (hurdling posture) hip flexion. This causes the fetal hooves (hoof) to push against the pelvic brim during attempts at fetal extraction.[418] The unilateral posture is more common. One can inflict severe trauma on the mare if one does not recognize this malposture and applies inappropriate amounts of traction. Thus one must stop all traction and repel the fetus enough to sweep the floor of the pelvic inlet. In extreme cases, the hindlimb actually may extend under the fetus and up into the vagina.[339] Although one may repel the hindlimb successfully if the fetus is alive, the procedure is difficult and is associated with some risk of uterine laceration. Judicious use of a snare or fetatome may facilitate safe repulsion of the hindlimb by looping the pastern and using the instrument to repel the hoof away from the pelvic brim. One should not attempt repulsion on a standing mare if the fetus is dead, because the hindlimb may not return to its normal position.[428,430] In such cases the hoof of the flexed hindlimb can puncture the ventral uterine wall on extraction of the foal. If a dog-sitting/hurdling foal is dead, use of general anesthesia and hoisting of the hindquartersis recommended to reduce the risk of ventral uterine rupture.[434] In experienced hands, partial fetotomy is a viable alternative to cesarean section.[428–430] A surgical alternative to a cesarean section involves manipulation of the hindlimb through a ventral midline celiotomy incision. An assistant

may be able to extract the fetus through the vagina once the hindlimb has been grasped throughthe ventral incision. If successful, this technique reduces the potential for contamination that may be associated with cesarean section. If a cesarean section is necessary, some surgeons prefer to remove that portion of the foal that is protruding through the vulvar lips before withdrawing the hindend out through the surgical site.[435]

In a foot-nape posture, one or both of the forelimbs will be displaced over the head of the foal and pushed against the roof of the vagina. To correct this malposture, one must repel the fetus into the uterus by applying pressure to the head. Once the forelimbs have been replaced under the head, fetal extraction can proceed uneventfully.[418] If the malposition is not corrected immediately, the straining of the mare can cause the fetal hoof to lacerate the vaginal roof and in extreme cases can result in a rectovaginal fistula. A fistula is all that occurs if the foal withdraws its hoof from the rectum before delivery. A third-degree perineal laceration occurs if the strong expulsive efforts of the mare cause the limb that has penetrated the rectum to dissect through the caudal rectovaginal shelf and rupture through the anal sphincter, thereby creating a cloaca.[436–438]

Carpal flexion may be uni- or bilateral, and typically the affected carpus is located at the pelvic inlet.[418] To correct this malposture safely, one first must repel the fetal body into the uterus. If the dystocia is prolonged, the amount of uterine contraction may preclude meaningful repulsion of the fetus back into the uterus. Because the fetus is likely to be dead in these cases, one can make a simple fetotomy cut at the level of the distal row of carpal bones. This permits safe delivery of the foal without the need to traumatize the reproductive tract and generally facilitates extraction within minutes.[428,430] If the foal is alive, then repulsion back into the uterus permits one to grasp the flexed limb at the level of the fetlock and pastern. By rotating the wrist, one can rotate the carpus laterally while bringing the flexed fetlock medially and caudally into the birth canal. This maneuver allows maximal use of available space by obliquing the extremity through the pelvic inlet. The obstetrician should be aware that flexural deformities are considered to be the most common congenital anomaly of foals and that the rigid deformity often means that one must perform a cesarean section or fetotomy.[181,223,412,428–430] Limb contractures are generally bilateral. Contracture is more common in the forelimbs than in the hindlimbs but can involve all four limbs.[412,418] One cannot straighten severely affected limbs, and one can inflict needless trauma on the genital tract by unrewarding attempts to correct the malposture manually. The clinician must cup a hand over the bottom of the fetal hoof at all times while attempting to straighten the limb. Failure to do so may result in injury to the reproductive tract. Application of an obstetric chain or rope to the distal limb can be a useful aid and permits application of traction to the distal limb while the hand covers and guides the hoof.[418]

The single most common abnormality in referral hospital dystocia populations is a reflected head and neck.[339,353,412] Unfortunately, these malpostures are often iatrogenic in that a viable fetus has pulled back from the initial vaginal intervention that aimed to correct a minor postural problem. If the mare strains while the head of the foal is pulled back, the muzzle possibly may engage the wall or floor of the pelvic inlet. The forceful expulsive efforts of the mare then may drive the head and neck ventrally, or laterally
along the thorax, while pushing the forelimbs further into the vaginal canal. Ventral or lateral 1109
displacements of the head and neck can be difficult to correct. The length of the neck of the foal often 1110
makes reaching the head impossible. Inexperienced clinicians should consider referral on diagnosing the condition, because prolonged unrewarding manipulations easily can jeopardize the future fertility of the mare.[418] A simple fetotomy cut can resolve these cases atraumatically if the fetus is dead when the veterinarian arrives. The author believes that this approach is preferable to prolonged, and often

unsuccessful, attempts at manual correction of this difficult malposture.[428] If the fetus is alive, one can attempt to place eye hooks or to loop a snare around the mandible. Some obstetricians even suggest applying a clamp on an ear to pull the head back enough to place a snare. Whenever possible, the author prefers to use a snare. If one can apply traction to the head, one can repel the body of the foal carefully while attempting to bring the head and neck around into a normal posture for delivery. Factors influencing the successful outcome include uterine tonicity, clinician arm length and skill, and the presence or absence of torticollis and facial scoliosis. As with contracted tendons, the practitioner must consider the possibility of a wry neck. This condition is not amenable to correction by mutation, and one can inflict needless trauma on the genital tract by unrewarding attempts at correction. Ventral deviation of the head is easy to correct if the fetal nose is just below the brim of the pelvis (poll posture). Generally, rotating the head laterally before attempting to bring the muzzle up over the pelvic brim is easier. In more severe cases the neck is tucked down between the forelimbs and the head often cannot be reached (nape posture).[412,418] If attempts to reposition the head and neck are unsuccessful, then cesarean section or fetotomy is indicated.[422,428–430]

Shoulder flexion posture may be unilateral (swimming posture) or bilateral (diving posture).[412,418] To gain access to the retained limb, one usually must repel the head and neck back into the uterus. An immediate cesarean section may be preferable if the foal is alive because correction of this malposture can be difficult and time-consuming. If cesarean section is not an option, then placing a soft rope snare on the fetal head (behind ears and into mouth) is recommended so that one can retrieve the head readily after correction of the shoulder flexion. If one can reach the limb, one corrects this malposture in two stages. Initially, one converts the shoulder flexion to a carpal flexion by grasping the limb in the area of the humerus and working down to the distal radius. One then pulls the limb caudally and medially while repelling the fetal body. One then hooks the carpus over the brim of the pelvis to create a carpal flexion, which one then corrects as directed previously. One must remember that repulsion of the head sufficient to gain access to the retained forelimb is not always possible. In these cases cesarean section is the only option for delivery of a live foal. If the fetus is dead, a fetotomy cut to remove the head and neck may provide sufficient room to correct the malposture.[428–430]

16.8.10.4.2

Caudal (Posterior) Presentation

A foal in posterior presentation has the soles of the hooves facing upward. Although the author has seen dystocias in which an anteriorly presented foal was in dorsopubic position with both forelimbs extended, this is an unusual complication. One should instruct foaling attendants to wash the perineum of the mare and to use a clean arm to check for the hocks somewhere in the vaginal canal. Gentle traction on the hindlimbs along with the expulsive efforts of the mare may facilitate delivery of a live foal. However, approximately half of the fetuses may be malpositioned as well and often require veterinary assistance to permit an atraumatic delivery. Foals in caudal (posterior) presentation are more likely to be in dorsoilial position than are foals in a cranial (anterior) presentation.[339] Although a normally positioned fetus in caudal presentation may not be that difficult to deliver, the foal is more likely to suffer hypoxia because of compression of the umbilical cord under the fetal thorax or because of premature rupture of the umbilical cord.[418] Although only about 1% of foals are presented posteriorly, this malpresentation accounts for 14% to 16% of referral hospital dystocia cases because any postural abnormalities create a major complication. Typically both hindlimbs are involved, and these types of dystocia cases (hock flexion, hip flexion) are difficult to correct under field conditions. Hock flexion malposture accounts for about one fourth of referred posterior cases.[339,353,412] Correction of a hock flexion is dangerous because of the risk of

perforation of the dorsal aspect of the uterus. One must repel the fetus into the uterus while pushing one hock dorsolaterally and directing the distal limb medially. The procedure for obliquing the extremity into the birth canal is similar to that previously described for correction of a carpal flexion. One can use an obstetric chain or strap to apply traction to the limb while cupping the hoof in the hand. Straightening a flexed hock entails considerable risk because the hock invariably is forced against the dorsal uterine wall. In cases in which the uterus is contracted, a real possibility exists of causing a laceration or perforation. Cesarean section may be preferable for delivery of a live fetus. This author strongly believes that fetotomy is a safer procedure than attempts at mutation if the fetus is dead.[422,428–430] Approximately half of referred posterior presentation cases are breech (bilateral hip flexion posture).[339,353,412] A cesarean section is indicated if the fetus is alive because the manipulations involved in correcting this malposture are time consuming and difficult. The comments for managing a hock flexion apply because if one attempts 1110
mutation, one must first convert the hip flexion into a flexed hock posture.[418] A key point is to remember 1111
to flex both hocks before attempting to straighten a limb. If one limb is extended into the vaginal canal while the other hip remains flexed, the fetal body will move back into the pelvic canal, and this will make accessing the retained limb difficult.[431] If the fetus is dead, the author recommends attempting to convert the bilateral hip flexion into a hock flexion posture, followed by correction with two fetotomy cuts through the distal row of tarsal bones. This procedure may be safer and cause less trauma than attempting to straighten the limbs, provided that the clinician is experienced in using a fetatome.[429] Attempts to correct a bilateralhip flexion by fetotomy, without first creating a bilateral hock flexion, are often unrewarding because of difficulty in correctly placing the fetotomy wire. Referral for cesarean section often provides the best prognosis for future fertility in these cases.

16.8.10.4.3 Transverse Presentation

Only about 1 in 1000 foals present transversely. Successful resolution of these dystocia cases requires a significant amount of obstetric experience, which explains why these rare presentations account for 10% to 16% of referral hospital dystocia cases.[339,412] Most transverse presentations are ventral transverse with the abdomen and limbs of the fetus presented toward the birth canal.[339,353,412] Although the widespread adoption of ultrasonography has reduced the likelihood of a twin birth greatly, one always must explore this possibility when more than two limbs are present in the birth canal.[181,223] In some instances, one possibly may repel the head and forequarters of the fetus while extending the two hindlimbs into the pelvic canal. If the manipulations are successful, the transverse presentation thus is converted into a posterior presentationfor vaginal delivery. The likelihood of successfully resolving one of these cases improves if one has anesthetized the mare and elevated the hindquarters.[418] Transverse presentations may be associated with flexural limb deformities, angular limb deformity, and spinal deformity. If thefetus is alive, the delivery method of choice is cesarean section.[422] Dorsal transverse presentations, with the spinal column of the fetus presented toward the birth canal, are rare. These cases warrant an immediate referral for cesarean section, even if the foal is dead.[339,353,412] Although an experienced obstetrician may be able to deliver a transversely presented fetus by fetotomy, the owner should be advised that this is a difficult and time-consuming procedure, with a high risk of trauma that likely will impede the future fertility of the mare.[418,428–430]

16.8.10.4.4 Fetal Anomalies

Hydrocephalus is not uncommon in equine fetuses, especially in pony breeds.[353,412] The condition occurs when increased intracranial pressure causes the bones of the skull to enlarge, sometimes almost doubling the size of the head.[412] The skull is often thin, and many affected foals can be delivered after incising the soft portion of the skull with a finger knife, allowing the skull to collapse. The trunk of the hydrocephalic fetus is generally smaller than normal and seldom interferes with delivery.[418] If the enlarged cranium is bony, then a fetotomy cut may be necessary to reduce the size of the head.[428–430]

16.8.11 Care of the Postpartum Mare

One should examine the fetal membranes as a matter of routine to ensure that they have been passed intact and to check for any placental anomalies that may forewarn of impending problems in the neonate. Often the chorioallantois has tears that can be misleading, especially ifthe mare has trodden on the membranes repeatedly. Examining the allantoic side of the membrane may be helpful in that one can piece together the blood vessels, which will give some idea as to whether a portion actually is missing.[292] Ideally, all foaling mares should receive a brief physical examination within 24 hours post partum. If the attitude of the mare is normal and she displays typical maternal behavior toward the foal, then one should check the udder and inspect the perineal area for evidence of trauma.[439] A detailed reproductive examination is usually unwarranted because it unnecessarily may disrupt the normal mare-foal bond that is developing at this time. All mares should receive a thorough reproductive examination at the foal heat.[337] Occasionally, one may detect an enlarged ovary, which may be a granulosa-theca cell tumor that has enlarged during the course of the previous pregnancy. Prompt diagnosis and surgical intervention may permit the mare to resume normal cyclicity and to conceive during the current breeding season.

Abdominal discomfort in the peripartum mare may be due to uterine contractions, especially if the mare has been treated with oxytocin to promote passage of the fetal membranes. However, one should not discount other causes of abdominal pain.[350,440–442] When a postpartum mare displays abdominal discomfort, this author believes that abdominocentesis is indicated. The normal foaling process does not alter the composition of the peritoneal fluid from within the normal range. Even a dystocia does not necessarily cause significant changes in the peritoneal fluid. If an experienced obstetrician performs the vaginal manipulations and/or fetotomy, the fluid should remain normal. If the peritoneal fluid is normal, then one should monitor the mare closely for signs of clinical deterioration. Repeated abdominocentesis may be indicated in cases in which clinical signs suggest that a parturient-related abdominal lesion may be present, because the peritoneal fluid constituents can change 1111
within hours. A single, elevated peritoneal fluid value (total protein, white cell count, or percent neutrophils) 1112
may be an incidental finding. Elevation of two or more values often signals the onset of clinical abnormalities. The author's experience has been that if a postpartum peritoneal fluid sample has total protein greater than3.0 g/dl along with a white blood cell count greater than 15,000 cells/μl and white blood cell differential count of greater than 80% neutrophils (especially if degenerative changes are present), then the presence of a potentially life-threatening lesion is likely.[350] One should not view the peritoneal fluid analysis in isolation and must consider it along with the history and clinical signs exhibited by the mare. In this author's experience, detection of changes in the peritoneal fluid almost invariably indicates the presence of foaling-related trauma in the reproductive or gastrointestinal tract. An early diagnosis followed by appropriate medical or surgical intervention often results in a favorable outcome. If treatment is not implemented until the affected mare has

become depressed and febrile, with accompanying signs of shock and toxemia, the prognosis may be more guarded.

16.8.11.1 PERIPARTURIENT HEMORRHAGE

The arterial supply to the uterus is supported by the mesometrium (broad ligament). The major blood supply to the uterus is from the uterine artery, a branch of the external iliac artery. The uterine artery forms a cranial branch that supplies the proximal uterine horn and a caudal branch that supplies the distal uterine horn and uterine body. The smaller ovarian artery gives off a uterine branch that anastomoses in the proximal horn with the cranial vessels from the uterine artery. The urogenital artery is a branch off the internal pudendal artery and gives rise to the caudal uterine artery along with vessels to the rectum, ureter, bladder, urethra, and vagina. The caudal uterine artery supplies the lateral side of the cranial vagina and continues past the cervix to ramify on the uterine body where it anastomoses with the caudal branch of the uterine artery.[3,443,444] Hemorrhage from these vessels, especially the large-diameter uterine artery, is a significant cause of periparturient colic signs and death in older, multiparous mares.[*] The condition occasionally may occur before foaling. In a study of 98 postpartum deaths, almost 40% were caused by uterine artery rupture. The rupture may be anywhere along the vessel and is typically 2 to 3 cm long and oriented parallel to the long axis of the vessel. Generally, no evidence of a predisposing aneurysm is apparent.[442] An association with low serum copper levels has been proposed as a reason for vessel fragility in aged mares.[448]

A predilection appears to exist for right-side uterine vessel rupture. The extent of cecal displacement of the gravid uterus to the left has been suggested to be sufficient to place increased tension on the vessels in the right broad ligament.[442,447] Although the added stress of dystocia may increase the chances of arterial rupture, many cases occur in mares that appeared to have an uneventful delivery.[423,442] Hemorrhage from the hypertrophied vessels that supply the gravid uterus may be rapidly fatal, especially if the artery ruptures directly into the peritoneal cavity. The mare may be found dead or moribund with pale mucus membranes, tachycardia (up to 140 beats/min), and tachypnea. Heroic attempts to administer blood transfusions, plasma expanders, and associated fluid therapy may save the life of some valuable mares, but costs are often prohibitive.[242,337,423] If the bleeding is contained within the broad ligament, the mare may be trembling and exhibiting signs of extreme pain (anxiety, sweating, colic), presumably because of the stretching of the broad ligament as the hematoma develops.[337,425,442] The color of the mucous membranes may not change initially because of vascular compensation, and often these initial colic signs are mistaken for the typical discomfort experienced by postpartum mares as the uterus contracts. However, if significant hemorrhage is present, the color of the mucous membranes eventually becomes pale, and capillary refill is delayed.[425] One must monitor these mares closely because the hematoma subsequently can rupture out of the mesometrium and lead to rapid exsanguination.[447]

If one suspects a ruptured artery, then one should not disturb the mare any more than necessary to perform an examination.[449] In many cases, postponing or even forgoing palpation per rectum may be prudent. Although an internal examination reveals valuable diagnostic information, transabdominal ultrasound, abdominocentesis, and a hemogram may be all that is necessary to confirm that an acute hemorrhagic episode has occurred.[337,439] Transabdominal ultrasonographic evaluation reveals free blood in the abdominal cavity if the hematoma has torn the broad ligament.[242] If broad ligament tears following a uterine artery rupture, then invariably a bloody tap results, with an elevated red blood cell count in the peritoneal fluid.[350] The centrifuged sample has a pink or hemolyzed appearance if hemoperitoneum is present. A smear that

reveals phagocytosed erythrocytes indicates hemorrhage rather than contamination during sampling. Even if a clot has contained most of the hemorrhage within the broad ligament, often considerable amountof blood is lost into the peritoneal cavity. The initial hemogram during an acute hemorrhagic episode can be confusing because the loss of erythrocytes and plasma may not alter the hematocrit immediately. Splenic contraction also temporarily raises the hematocrit.[242] In the author's opinion, one should not transport these mares 1112
because movement could destabilize the clot and prove to be fatal. One should administer any supportive 1113
therapy at the stall until the mare has stabilized. One should keep the foal safely nearby so that the mare does not become unduly distressed.

Most recommendations for managing postpartum hemorrhage in mares are based on the collective wisdom of experienced clinicians and from methodologies that have been extrapolated from the human trauma literature. The approach one takes is governed by the facilities and expertise available and especially the economics of the case at hand. In some instances an extreme hypotensive state may actually offer the best chance for survival (conservative approach), whereas in other cases an attemptto restore intravascular pressures and circulatory volume could be indicated. The conservative approach is to confine the hypotensive mare to a dark, quiet stall with minimal disturbances. In some cases a platelet-fibrin plug seals the rent in the vessel once the arterial pressure falls. One should use tranquilizers (especially acetylpromazine) with caution because any induced drop in blood pressure may exacerbate the hypovolemic shock. Some clinicians use “hypotensive resuscitation” by administering a vasodilating agent along with intravenous fluid therapy. The idea in this instance is to provide life-saving volume replacement while maintaining a low mean arterial pressure. In life-threatening situations, anything that may stabilize the mare is worthwhile, but the clinician should consider the possibility of impeding resolution of the hematoma by rapid expansion of blood volume and elevation of blood pressure. The need to support cardiac output and ensure oxygen delivery must be balanced against the prospect of the increased arterial pressure promoting further hemorrhage.[242]

Although the costs can soar rapidly, an aggressive therapeutic approach occasionally can save the life of a valuable mare.[242,442,450] If a valuable mare presents in shock and appears to be deteriorating rapidly, then one should insert a large intravenosus catheter and begin substantial fluid therapy. One must give whole blood transfusions slowly and thus they are of little benefit for resuscitative purposes when rapid volume expansion is required. One option is rapid administration of 2 to 3 L of hypertonic saline, followed with 10 to 20 L of lactated Ringer's solution over a period of 2 to 4 hours. An alternative to the hypertonic saline is the high oncotic pressure exerted by colloids (e.g., 3 L hetastarch). Synthetic oxygen-carrying fluids are commercially available but extremely expensive. One can provide supplemental oxygen via nasal insufflation at a flow rate of5 to 10 L/min. If the hematocrit continues to drop to under 15%, then whole blood transfusions (6 to 8 L over several hours) may be warranted.[242] Benefits include provision of oxygen-carrying cells, clotting factors, and oncotic pressure (albumin).

A shock dose of corticosteroid is indicated. Because hemorrhagic shock can cause ischemic-reperfusion damage to the gut and lungs (multiple organ failure), broad-spectrum antibiotics, antioxidant drugs, and antiinflammatory medication may be warranted if the mare survives the initial hemorrhagic crisis. One administers flunixin meglumine (1.1 mg/kg) to reduce the inflammatory cascades activated by ischemia, and this may help to alleviate the discomfort of the mare. Low-dose (10 to 20 IU) oxytocin therapy may be useful to promote uterine involution and thereby reduce the weight supported by the ligaments. One should avoid higher doses becausean induced colic episode may precipitate a fatal hemorrhage. Antifibrinolytic drugs (aminocaproic acid; tranexamic acid) may assist with clot stabilization. Pentoxifylline increases erythrocyte flexibility and may increase oxygen delivery to ischemic tissues.[242] One should remember that little in the refereed veterinary literature validates the use of some of these medications in the horse. For instance, a

conjugated estrogen product has been proposed, based on its ability to shorten prolonged bleeding times in human beings. However the benefit, if any, would not be realized until several days after the crisis has passed. Likewise, anecdotal reports suggest that naloxone (8 mg) may be efficacious, but the concept has been extrapolated from small animals, and controlled equine studies are lacking.[242,337,423] A controversial historical therapy to promote hemostasis in the horse is the use of intravenous buffered 10% formalin. Advocates suggest that dilute formalin solutions could enhance the activation of the clotting cascade. However, recent controlled studies were not able to demonstrate an effect on coagulation parameters or template bleeding times in normal horses.[451] One should administer broad-spectrum antibiotics to prevent infection of the hematoma.[445]

If hemorrhage is contained within the wall of the uterus, then the intramural hematoma may be an incidental finding at the foal heat examination. However, some mares may exhibit variable signs of abdominal discomfort, even to the extent of warranting an exploratory celiotomy.[423,436,452–454] If an endometrial laceration severs an artery in the uterine wall, then substantial hemorrhage may ensue, often with blood escaping from the vagina. One should confine the mare to a stall and institute low-dose oxytocin therapy. Uterine irrigation is contraindicated because it disrupts clot formation and prolongs the hemorrhagic episode. The internal pudendal artery, one of the terminal branches of the internal iliac artery, gives rise to the umbilical artery and the urogenital artery before terminating in branches to the perineal area and the vestibular bulb. The small cranial vesicular artery supplies the apex of the bladder before the remainder of 1113
the umbilical artery terminates into the cordlike round ligament of the bladder. The urogenital artery gives 1114
rise to a caudal uterine branch that runs cranially on the side of the vagina and ramifies with the caudal branch of the uterine artery on the body of the uterus. The urogenital artery also supplies branches to the rectum, ureter, caudal bladder, and urethra and continues as the vaginal artery to the caudal portion of the reproductive tract.[3,443,444] A hematoma arising from these vessels may dissect along the fascial plane within the pelvic cavity and present as a large unilateral vulvar swelling.[425] Affected mares typically experience violent colic. Abscessation of a retroperitoneal hematoma can become a life-threatening complication following a dystocia, and thus prophylactic broad-spectrum antibiotic coverage is warranted.[442] Mares with an infected retroperitoneal hematoma develop signs of toxemia. In these cases the peritoneal fluid has an increased total protein content (3.0 to 5.0 g/dl) with a massive increase in the white blood cell count (often exceeding 100,000 cells/μl).[350]

16.8.11.2 UTERINE PROLAPSE (EVERSION)

Uterine prolapse is an uncommon complication of equine parturition that may occur up to several hours (and occasionally several days) after fetal delivery.[423] The condition may be complicated by bladder eversion or prolapse, uterine rupture, or intestinal herniation and may be rapidly fatal if the uterine artery ruptures.[*] If the mare is standing and personnel are available, one should give instructions to place the uterus in a large plastic bag and elevate it to the level of the vulva. This may prevent further damage to the endometrium and more importantly will relieve the tension on the uterine vessels. Fluid therapy may be indicated, and any calcium deficit must be corrected. Epidural anesthesia may reduce the amount of reflex straining provoked by vaginal manipulations but will not eliminate the strong abdominal press of the mare.[419] General anesthesia may be necessary if the mare exhibits violent discomfort or if straining is excessive. One should close any uterine lacerations with absorbable sutures. One then “kneads” the well-lubricated uterus back through the vagina. The finger tips easily can damage the edematous tissue, and manipulating the uterus

through a plastic bag reduces the likelihood of a finger rupturing the wall.[337,455] Ultrasonography is useful to evaluate any suspicious contents. One may aspirate a trapped bladder through a large-diameter needle, but a loop of bowel may require a ventral midline celiotomy.[445]

One should distend the replaced uterus with sterile saline to ensure that the tips of both horns are extended fully. One should administer repeated low doses (10 to 20 IU every 2 hours) of oxytocin to promote uterine involution. Failure to ensure complete extension of the uterine horns into a normal position within the abdomen may result in discomfort, straining, and recurrence ofthe prolapse.[337] Vulvar retention sutures should not be necessary, provided that the uterus has been returned completely to its normal position, that the calcium deficit has been corrected, and that low-dose oxytocin therapy has been administered. Broad-spectrum antibiotics, nonsteroidal antiinflammatory drugs, and tetanus prophylaxis are indicated. One should monitor the mare closely for evidence of internal hemorrhage. Affected mares may exsanguinate after the uterus has been replaced. Ischemic damage to trapped bowel is a potential complication. The clinician should be cognizant of the potential risks of endometritis/metritis, septicemia, endotoxemia, and laminitis. Two to 3 days of intrauterine therapy may be warranted, depending on the condition of the exposed endometrium.

16.8.11.3 PARTIAL INVERSION (INTUSSUSCEPTION) OF THE UTERINE HORN

Injudicious traction on a retained fetal membrane remnant may invert the tip of the uterine horn, and this may progress to complete uterine prolapse.[337] If only the horn is affected, then compromised circulation and pressure on nerve endings may produce signs of abdominal discomfort. Thus one should palpate the tips of both uterine horns per rectum when evaluating a postpartum colic case. The affected horn is shorter than normal and extremely thickened.[439,445,456] Manual reduction by pressure from within the uterine lumen may be possible in some cases, and infusion of several liters of saline solution usually ensures extension of the affected horn.[439] One then should administer oxytocin (10 to 20 IU) and drain the fluid from the uterus as it contracts. One should confirm resolution of the problem by palpation per rectum.

16.8.11.4 UTERINE RUPTURE

In any dystocia case a risk for iatrogenic tears exists, and one always should check the uterus for any obvious lacerations immediately after extraction of the fetus. Early recognition is important because the prognosis is worse once peritonitis develops.[350,424,425,442] However, obstetric intervention is not always the cause of uterine tears. Occasionally, a hoof of the foal may be forced through the dorsal uterine wall during the expulsive efforts of the mare, and the mare may be found with a loop of bowel protruding through the vulvar lips.[349,423] One should rinse the exposed bowel with sterile saline and replace it, but a ventral midline celiotomy may be warranted to evaluate intestinal damage fully and to repair the uterine laceration. A more 1114
common lesion in unassisted deliveries is a tear toward the tip of the gravid uterine horn. Although the fetal 1115
hooves are covered with hard gel-like pads that presumably protect the placenta and uterine wall, the vigorous pistonlike thrusts of the hindlimbs occasionally may cause a rupture.[4,287,457] Affected mares generally experience bouts of colic and become depressed, febrile, and anorectic as peritonitis develops. The interval from occurrence of the tear to diagnosis and initiationof therapy has a significant affect on the prognosis for survival.[337,350,425,442,458] Ascertaining the uterine integrity by vaginal palpation alone may not be possible.[425] The tips of the horns may be especially difficult to palpate from within the postpartum uterus. The changes in the peritoneal cavity depend on the duration of the condition, but generally one can expect to

see serosanguinous to sanguinous fluid containing elevated total protein, increased white blood cell counts, and often extracellular and intracellular bacteria.[350,427,458] Laparoscopic evaluation of the uterus may confirm the diagnosis and provide useful information to determine whether surgery is indicated.[459] Complete perforation of the uterine wall is not necessary for peritonitis to develop if traumatic obstetric manipulations have damaged the uterine wall.[460] However, recent research has proved that even a fetotomy procedure does not alter the composition of the postpartum peritoneal fluid if it is performed correctly.[350]

If one suspects a uterine laceration (partial or full), the mare should receive systemic broad-spectrum antibiotic coverage. Nonsteroidal antiinflammatory medicationmay prevent the development of endotoxemia. Oxytocin therapy (10 to 20 IU every 2 hours) promotes uterine involution. One can increase the dose if the mare does not become uncomfortable. One should administer fluid therapy as necessary, ensuring that calcium levels are within the normal range. Intensive medical management may suffice for small dorsal uterine tears, but most warrant suturing if costs are not a limitation.[458,459] Opinions vary on the need for and usefulness of peritoneal lavage.[459] Large, full-thickness tears warrant surgical intervention. In some instances, one can suture a laceration in the uterine body blindly in situ, but often a ventral midline celiotomy is the preferable approach.[337,351,424,458]

16.8.11.5 RETAINED FETAL MEMBRANESAND TOXIC METRITIS

Once the umbilical cord ruptures, blood flow through the capillary network in the placenta suddenly ceases.[159] This causes a reduction in the tissue volume of the microcotyledons, and the rhythmic tubocervical contraction waves cause the membrane tips to separate and invaginate into the horn. The ongoing tubocervical detachment process causes the membranes to be passed inside out, with the allantoic surface exposed. The membranes should be expelled within 3 hours post partum, and the incidence of retention has been reported to range from 2% to 10% of foalings.[338,445,461,462] Membrane retention tends to be associated most commonly with the tip of the nongravid horn, and appears to be associated with dysfunction of the initial separation process.[23] In circumstances in which tissue inflammation is common (abortion, dystocia, cesarean section), membrane retention is more likely to occur. In these cases the endometrial edema may trap the microcotyledons within the endometrial crypts. Mares with membrane retention may have a significantly lower serum calcium level.[463] A recent study noted that the number of endometrial mast cells observed during the puerperal period is significantly lower in the endometrium of mares with retained fetal membranes.[464] Some dysfunction of the normal endocrine-related maturational processes within the microcotyledons likely is involved.

Appropriate management of a mare with fetal membrane retention varies depending on the time since foaling.[465] Although some mares, especially those foaling in a natural environment, may not experience any complications, prophylactic medication is recommended under intensive husbandry conditions.[462,466] Bacterial contamination in this environment is highly likely. If a severe metritis develops, inflammation of the uterine wall permits bacteria and toxins to enter the systemic circulation, producing septicemia and endotoxemia.[460,467] Laminitis is a frequent sequela.[337] The approach to treating retained fetal membranes varies considerably, depending on the duration of membrane retention and the presence or absence of metritis with septicemia. In normal, unassisted foalings, one or two treatments with oxytocin may be all that is required to facilitate passage of the retained membranes. One should tie the protruding placental remnants in a knot above the hocks of the mare. An initial, low dose (10 to 20 IU) of oxytocin is recommended because some postpartum mares can be especially sensitive to this hormone and may experience a severe bout of

colic within minutes of treatment. Higher doses are likely to be counterproductive because myometrial spasm occurs instead of the desired rhythmic, tubocervical contractions. If colic does occur, one should sedate the mare so that she does not roll and possibly injure the neonate.[337] In these cases, one should reduce the next dosage of oxytocin. The response of each mare to the initial treatment governs the subsequent dose recommendations: 10 to 20 IU incremental increases every 2 hours.

The author routinely distends the chorioallantoic sac with fluid after any obstetric procedure. This procedure, known as the Burn's technique, has promoted membrane expulsion (5 to 30 minutes) in most postdystocia mares that the author has managed. A major advantage is that expulsion of the intact fetal membranes removes any contaminants that may have been introduced by the obstetric procedures.[468] The technique only 1115
works if one can pass a sterile nasogastric tube beyond the torn distal fragments and is best performed while 1116
the membranes are still fresh. In more protracted cases the rapidly autolyzing chorioallantois becomes friable and generally tears once the fluid pressure increases. To perform the procedure, one tightly holds the exposed fetal membranes around the tube while infusing 12 to 15 L of solution. One then ties off the opening with umbilical tape. The exact mechanism is unknown, but expansion of the uterine lumen may dilate the endometrial crypts such that the weight of the membranes can pull the microcotyledons free atraumatically. One can supplement endogenous oxytocin release to enhance uterine contractions.

Because the uterine response to oxytocin wanes during the postpartum period, the dose may be increased in small increments every 2 hours in those mares that retain their fetal membranes despite the initial therapy. If a hospitalized mare is receiving intravenous fluids, then one can add each oxytocin treatment to the fluid line. Another option is to add oxytocin to the fluid bag ata dose that is calculated based on the flow rate (1.0 IU/min).[337] However, a disadvantage of this approach is that one must discard these fluids if the mare becomes uncomfortable yet still requires rehydration. The calcium ion plays a vital role in myometrial contractility, and one must ensure that calcium levels are within the normal range.[383,469] Supplemental calcium can expedite the rate of passage greatly, suggesting that uterine hypomotility is a component in some of these cases.[463] Controlled exercise is often beneficial in promoting uterine involution but is not always feasible if the mare is hospitalized or is being kept in a stall while a compromised neonate is being medicated.

Excessive traction on the fetal membranes is accepted widely as being contraindicated, but a recent study suggests that cautious manual removal of the membranes may not be as deleterious as previously thought.[470] When one extracts the membranes by force, inevitably disruption of the epithelial barrier occurs, making the traumatized uterine lining more susceptible to bacterial invasion and the development of metritis.[467] Endometrial trauma is also likely to contribute to the development of periglandular fibrosis. For the membrane tip to tear off and remain firmly attached within the nongravid horn is not uncommon.[23] Injudicious traction on the membranes also can cause an inversion of the tip of the uterine horn, and this can progress to a complete uterine prolapse.[337] If the fetal membranes have not been expelled after a couple of days of supportive therapy, the autolytic tissue becomes less firmly embedded and a gentle twisting technique, with minimal traction, applied within the attached horn often results in successful removal of the entire chorioallantois. In the author's experience, this procedure works best while the uterus is being distended during a uterine lavage. Recent studies suggest that a safe and potentially effective treatment for retained fetal membranes in mares may be intraplacental injections of collagenase.[471,472]

If the membranes have been retained for 6 to 8 hours when one first examines the mare, then systemic antibiotic therapy is indicated.[337] Drugs that have been recommended for systemic administration include ampicillin, gentamicin, kanamycin, penicillin, ticarcillin, and trimethoprim-sulfamethoxazole.[473] If a

remnant is missing when one examines the membranes, then the approach to therapy should proceed as if the entire membranes were still present. A mare with toxic metritis is characterized by fever, depression, anorexia, tachycardia, and injected mucus membranes.[467] The foal does not receive adequate milk intake, and many of these mares have bounding digital pulses and evidence of laminitis. Palpation per rectum reveals a large, thin-walled, atonic uterus that contains moderate to large amounts of fetid fluid.[337] A large volume of toxic, red-brown, watery fluid can accumulate within the pendulous postpartum uterus before any obvious vaginal discharge becomes evident. Often the history reveals that the fetal membranes were discarded without being checked that they were passed intact.

Because the endometrium is likely to be necrotic, therapy should include broad-spectrum antibiotics, antiinflammatory drugs, and intravenous fluids if indicated. Tetanus prophylaxis is advisable. A combinationof penicillin and gentamicin is used widely to provide broad-spectrum systemic coverage, especially against the coliforms that frequently contribute to endotoxemia and laminitis.[474] One should administer flunixin meglumine to ameliorate the effects of endotoxemia. The drug commonly is administered intravenously at a reduced dose (0.25 mg/kg) 3 times daily.[337] Phenylbutazone (2 to4 mg/kg) and provision of deep, soft bedding are useful to alleviate pain when laminitis appears to be imminent. Radiographs can be useful to monitor changes in the position of the pedal bone. One may administer vasodilators such as acetylpromazine maleate by intramuscular injection (0.02 to 0.04 mg/kg every 4 to 6 hours).[474]

One should lavage the uterus with sterile saline or very dilute povidone-iodine solution and should exercise extreme caution to avoid puncturing the inflamed uterine wall with the tube. If povidone-iodine solution is used, the final concentration should not exceed 0.1%; this is equivalent to 10 ml of 10% povidone-iodine solution (e.g., Betadine) in one liter of saline. One should repeat the lavage until the returning fluid is clear. The goal of therapy is to eliminate toxins and to prevent the rapid proliferation of bacteria, especially coliforms and possibly anaerobes. The administration of intrauterine antibiotics in the postpartum mare is 1116
controversial because little scientific validation has been performed. Intrauterine administration of antibiotics 1117
and antiseptics may depress the phagocytic activity of uterine neutrophils, and many chemicals are known to irritate the endometrium in mares being infused for endometritis.[473] The pharmacokinetic properties of each drug influence its efficacy in the postpartum uterus. Most of the studies regarding intrauterine therapy in mares have addressed therapy for endometritis in nonparturient animals. The efficacy of antibiotic formulations in the presence of the mixed bacterial population and tissue debris associated with fetal membrane retention in the mare remains to be established. One should add the antibiotic of choice to a large infusion volume (2 to 3 L) to ensure uniform distribution across the inflamed endometrial surface once a lavage has removed the toxic fluid and necrotic debris. Unpublished microbiologic studies in the author's laboratory have demonstrated that many organisms cultured from metritis fluid are sensitive to amikacin.[262] Infusion of 2 g of this antibiotic after a uterine lavage has proved to be clinically effective. Polymixin B may have some merit because of its endotoxin-binding ability. Powdered and propylene glycol–based oxytetracycline formulations are known to be irritant when infused into the involuted uterus and should be avoided.[475,476] Other antibiotics that have been suggested for postpartum intrauterine therapy include ampicillin (3 g), ticarcillin (1 to 3 g), and gentamicin (2 to 3 g).[477] In the author's unpublished studies, less than 60% of isolates from metritis fluid were sensitive to ampicillin.[262]

16.8.11.6 GASTROINTESTINAL COMPLICATIONS

Prolonged straining during a dystocia can lead to variable amounts of rectal mucosa being forced out through the anal sphincter (type I rectal prolapse). The tissue then becomes subject to trauma, contamination, and

vascular compromise. If one does not correct the condition promptly, pressure from the anal sphincter causes venous congestion and swelling, which promotes more straining, and the condition can deteriorate rapidly. A type II prolapse involves all or part of the ampulla recti.[438,478] An epidural anesthetic may help to decrease straining. One may apply topical glycerin or dextrose to the prolapsed tissue to reduce edema.[337,478] A purse-string suture can cause additional straining and impedes defecation.[478,479] One should administer fecal softeners and should modify the diet (pellets, pasture) to help produce soft feces. Chronic prolapses may warrant surgical resection of the devitalized mucosal mass.[478,480] In a type III prolapse a full-thickness rectal prolapse plus an intussusception of the peritoneal rectum or small colon occurs.[478] In a type IV prolapse the intussuscepted bowel protrudes through the anus such that a palpable trench that may extend several meters into the rectum, depending on the length of the intussusception.[415,416,478,479] Midventral celiotomy is usually necessary to reduce the intussusception, although some smaller prolapses reduce after an attendant has extracted the foal.[478] The short mesentery that supports this section of bowel often is torn fromthe colon. Thus these cases have a guarded prognosis, depending on the vascular integrity of the affected small colon. The author has seen this condition develop when as little as 6 to 10 inches of bowel appears to be prolapsed. The avulsion most likely occurs when the intermittent straining of the mare forces an extra 4 to 6 inches of bowel in-and-out of the rectum. Thus to prevent straining as soon as possible is imperative. If the foal has not yet been extracted, then immediate anesthetization of the mare may be best, followed with elevation of the hindquarters before attempting to correct the cause of the dystocia.

In rectal prolapse cases that have been managed conservatively, one of the first postpartum clinical signs may be discomfort attributable to impaction colic. If avulsion of the mesocolon has occurred, then ischemic necrosis of the affected bowel causes a delayed peritonitis. Because early intervention is essential, sequential abdominocentesis is indicated when one is managinga type III or IV rectal prolapse conservatively. Initially changes in the composition of the peritoneal fluidmay be negligible. However, if an avulsion has occurred, then the compromised segment of bowel soon looses its integrity and a massively increased white blood cell count can occur within 24 to 48 hours as peritonitis ensues.[350] Laparoscopic evaluation of the abdomen can provide an immediate assessment of bowel integrity and permitan accurate prognosis to be given to the owner.[352] The affected colon is not readily accessible for resection and anastomosis, so the prognosis in most cases is guarded.[480]

Variable degrees of uncomplicated impaction are not uncommon in the postparturient mare, possibly because of localized perineal pain causing reluctance to defecate.[337] Astute managers note an absence of fecal matter in the stall. Treatment with fecal softeners (e.g., mineral oil) and analgesics generally corrects the problem. Laxative feeds (e.g., bran mash) are effective in reducing the incidence of constipation in foaling mares.[439] Postpartum mares appear to be at an increased risk for developing a large colon torsion.[221,442,481] This condition presents as an especially violent colic with readily discernable abdominal distention. Extensive ischemic damage affects the prognosis, but early surgical intervention can increase the survival rate.[425,482] Bruising of the abdominal viscera can occur during foaling, with subsequent development of moderate to severe signs of impaction colic and peritonitis.[423,425] Occasionally the mesentery may be torn from a 1117
segment of intestine, leading to ischemic necrosis and peritonitis. An early diagnosis and prompt surgical 1118
intervention may save the life of the mare.[350,352,440–442,483] A rent in the mesentery or broad ligament at the time of foaling may permit a segmentof bowel to become incarcerated even weeks later.[218,436,441,442,484] One should advise owners that surgical correction is only feasible if the segment of devitalized bowel is accessible.[218,441,483–485]

Although mares tend to reduce their feed intake in the days leading up to foaling, ensuring a reduction in the amount of available roughage may help reduce the incidence of bowel rupture.[439] The tip of the cecum is the most likely site of a foaling-related rupture in the alimentary tract. On palpation per rectum the inflamed serosal surfaces feel roughened with a discernable crepitus. Abdominocentesis reveals dark green-brown gastrointestinal fluid that contains plant material and massively increased neutrophil numbers. Humane euthanasia is indicated because the leaking ingesta incites a severe peritonitis with accompanying septic shock, and the condition is likely to be rapidly fatal.[423,442,486–490] Diaphragmatic herniation has been reported as a rare parturient complication in heavily pregnant mares.[349,491–493] Colic symptoms are attributable to strangulating obstruction or tension on the mesentery. Some mares may exhibit respiratory distress. Transthoracic ultrasonography can help confirm the presence of bowel within the thorax.[494] Surgical repair of the defect may not be possible, and assisted ventilation is required.[492,493]

16.8.11.7 VAGINAL LACERATIONSAND BLADDER PROLAPSE

Primiparous mares are especially susceptible to vaginal trauma. Vaginal lacerations are most likely to occur during injudicious attempts to relieve dystocia. Although most lacerations are retroperitoneal, they still may contribute to severe vaginitis, fibrosis, and possibly abscessation. If ventral trauma is present, then one should pass a urinary catheter to check for urethral integrity. In some instances ligation of a severed artery is necessary. Emollient creams, tetanus prophylaxis, broad-spectrum antibiotics, and antiinflammatory drugs are indicated. A major concern is the possibility of herniation of intestine into the vagina if the tear is located just caudal to the cervix in the vicinity of the urogenital pouch.[442,495] If eventration has occurred, one should cleanse the bowel and examine it for evidence of vascular compromise. If the involved intestine appears to be grossly normal, then one should rinse it with sterile saline and return it to the abdominal cavity. If one detects vascular compromise at the time of the initial examination, then the prognosis is guarded and a ventral midline celiotomy to facilitate resection is warranted. A bladder prolapse occurs when the bladder is forced up through a vaginal laceration. The viscus rapidly becomes distended because of continued accumulation of urine from the ureters and an inability to void urine because of kinking of the urethra. The edematous serosal surface of the bladder may protrude through the vulvar lips.[337] One should clean the exposed organ thoroughly and then gently return it the abdominal cavity. Administration of an epidural and aspiration of urine to facilitate replacement may be necessary. If possible, one should suture the vaginal laceration once any viscera have been returned to the abdominal cavity. In some cases the severity of the trauma precludes successful closure, and the wound must heal by second intention.[495] Placement of a Caslick suture reduces the possibility of bacterial aspiration. Mares may be cross-tied for several days to decrease the risk of eventration brought about by increase of intraabdominal pressure as the mare lies down.[337] One should treat the mare for impending peritonitis (broad-spectrum antibiotics; nonsteroidal antiinflammatory drugs). Tetanus prophylaxis is indicated. If severe colic symptoms develop, then one should suspect bowel compromise.[350]

16.8.11.8 EVERSION OF THE URINARY BLADDER

The urethra of the mare has a large diameter, and occasionally the bladder may be everted up into the vagina following severe straining.[496] If the everted bladder protrudes through the vulvar lips, the exposed mucosal surface rapidly becomes edematous, and urine may drip from the ventral surface. Closer inspection reveals that the urine is dribbling from the exposed papilliform openings of the ureters on the dorsal surface of the

neck of the bladder.[497] A lip chain and epidural may provide adequate restraint to facilitate replacement. One should clean the mucosal surface thoroughly and repair any defects and then apply sterile lubricant and gently massage the friable organ back through the urethra. In some instances, incising the urethral sphincter may be necessary if the bladder mucosa is especially thickened.[497] One should close this incision after replacing the bladder. One can insert a Foley catheter to lavage the bladder lumen and to ensure complete repositioning. Broad-spectrum antibiotic coverage, nonsteroidal antiinflammatory drugs, and tetanus prophylaxis are indicated.

16.8.11.9 RUPTURE OF THE URINARY BLADDER

Occasionally the bladder may rupture as a consequence of increased intraabdominal pressure in the foaling mare or because of direct trauma during parturition.[498–500] Clinical signs are delayed and are associated with electrolyte imbalances. Affected mares may be depressed and inappetant, with failure to void urine. Clinical examination reveals tachycardia, tachypnea, and decreased gastrointestinal activity. Blood chemistry reveals elevated serum levels of creatinine, blood urea nitrogen, and potassium with decreased sodium and chloride 1118
levels. Evaluation of a peritoneal fluid sample helps to confirm the diagnosis. The fluid contains elevated 1119
urea and creatinine levels and calcium carbonate crystals.[498,499] Cystoscopy is useful to evaluate the size and extent of the bladder injury. Once one has stabilized the medical condition of the mare, surgical repair is indicated.[436,498–500] A standing vaginal approach eliminates the need for general anesthesia and allows excellent observation and repair of bladder tears in adult mares.[500]

16.8.11.10 RECTOVAGINAL FISTULAEAND PERINEAL LACERATIONS

A first-degree perineal laceration involves the mucous membrane of the vestibule and the skin of the vulvar lips. In second degree perineal lacerations the deeper tissues of the perineal body are involved. Both of these conditions may be associated with unassisted delivery of a large foal or may be sequelae of dystocia. The lacerationmay be amenable to immediate repair and placement of a Caslick suture, or the clinician may elect to wait until the wound has granulated. One should treat the mare with broad-spectrum antibiotics, antiinflammatory medication, and tetanus prophylaxis. Provision of a bran mash diet and administration of mineral oil may facilitate defecation during the initial inflammatory period.

Third-degree perineal lacerations generally occur during unassisted foalings when the fetal hoof catches on the vaginal roof at the vestibulovaginal junction. Forceful straining by the mare can drive the hoof through the rectovaginal shelf such that the fetal hoof comes to lie within the rectum. If the fetus is viable, it may remove the affected limb so that delivery proceeds unimpeded, and a rectovaginal fistula results. If the limb remains within the rectum, then continued passage of the fetus causes the trapped limb to tear out the perineal body and anal sphincter. The resulting defect is called a third-degree perineal laceration. These injuries do not respond well to immediate surgical intervention, and the general recommendation is to wait 4 to 6 weeks before attempting reconstructive surgery.[436,496] In the interim, one should treat the mare with broad-spectrum antibiotics, antiinflammatory medication, tetanus prophylaxis, and fecal softeners.

16.8.11.11 PERINEAL BRUISINGAND VULVAR HEMATOMAs

Much of the swelling after prolonged obstetric manipulations is edematous. Fecal softeners such as orally administered mineral oil or a bran mash are recommended to ease the passage of feces through the swollen

and bruised perineal area.[349,439] Hematomas in the vaginal wall and vulvar lips are not uncommon, especially in primiparous mares and in those mares that have delivered a large foal. One must differentiate a bulging vestibular hematoma from an everted or prolapsed bladder.[439,443] Needle aspiration of vulvar hematomas is not recommended because of the risk of abscessation. Broad-spectrum antibiotics and tetanus prophylaxis are indicated. Most hematomas resolve uneventfully, but some vulvar, vaginal, or pelvic hematomas may warrant drainage in7 to 10 days.[349]

16.8.11.12 POSTPARTUM ECLAMPSIA(LACTATION TETANY)

Postpartum eclampsia is rare in mares but may occur in animals that are lactating heavily. The highest incidence is reported to occur in Draft breeds, but the author has encountered a case in a pony mare. Equine eclampsia generally is associated with some type of stress (e.g., change in surroundings). Early signs include restlessness, tachypnea, staring eyes, twitching, trembling, and clonic spasms (especially diaphragmatic). The clonic spasms gradually become more tonic, and eventually the mare may be unable to stand. The differential diagnosis is tetanus, but the nictitating membrane is not prolapsed. The condition responds well to intravenous administration of calcium gluconate.[159]

16.9 16.9—Assisted Reproductive Techniques

Elaine M. Carnevale

Marco A. Coutinho da Silva

16.9.1 Assisted Reproductive Techniquesfor the Mare

Until recently, use of assisted reproductive techniquesin the mare has been limited; however, during the last decade, new methodologies have been developed and proven. New assisted reproductive techniques allow production of offspring from mares that are infertile using standard breeding techniques or embryo transfer.

16.9.1.1 OOCYTE TRANSFER

Although the first successful oocyte transfer was performed in 1988, the technique was not used for commercial transfers until the late 1990s.[1–3] Oocyte transfer involves the transfer of an oocyte from a donor into the oviduct of a recipient; the recipient is inseminated within the uterus. Fertilization, embryo development, and fetal development occur within the recipient, thereby avoiding problems associated with

ovulation or the tubular genitalia of donors. The incidence of ovulatory failure increases with age and during the autumn months.[4,5] Prolonged exposure to an abnormal follicular environment results in aging and death of the oocyte. One can detect some types of ovulatory failure with ultrasound as an atypical morphology of the follicle or ovulatory site. Mares that repeatedly fail to ovulate can provide oocytes for transfer successfully if oocytes are collected before deleterious changes occur within the follicle.[2]

Historically, the uterus has been considered the primary cause of reduced fertility in the mare. Mares with pyometras or persistent endometritis are expensive to treat and frequently do not provide embryos. Mares with problems such as cervical lacerations, cervical or uterine adhesions, or urine pooling often fail as embryo donors. However, oviduct dysfunction has been shown to be a major impediment to fertility, especially in aged mares. When the oviducts of old mares (>20 years) and young mares (2 to 9 years) were flushed between 1 and 4 days after ovulation, collection rates of recently ovulated oocytes or oviductal embryos were significantly higher in the young versus old mares (26 of 27, 96%, versus 17 of 29, 59%, respectively).[6] In subfertile mares, pathologic changes of the oviducts were imaged using scanning electron microscopy, and significantly fewer sperm were detected in the caudal isthmus in subfertile mares than in fertile mares. Few sperm found in the oviducts of subfertile mares were motile, whereas oviducts of the normal mares contained highly motile sperm.[7] Obstructions of the oviductal lumen have been postulated to be the cause of subfertility in some mares. Globular masses composed of type I collagen were found more frequently in older than in younger mares.[8] In another study, oviductal masses were found in the oviducts in 73% (16 of 22) of mares between 2 and 22 years of age; in a small number of mares (3 of 43), the masses occupied and distended the oviductal lumen and could have resulted in infertility. The equine embryo remains in the oviduct for 5 to 6 days before entering the uterus; therefore, oviductal problems such as inflammation could affect embryo viability.[9]

16.9.1.2 PROCEDURES FOR OOCYTE TRANSFER

Requirements for oocyte donors are minimal. If one detects intrauterine fluid collections or vulvar discharges in donors, one should culture the uterus and treat the mare to prevent introduction of a pathogen into the abdominal cavity during transvaginal oocyte collections. Donors should have regular estrous cycles with growth of a preovulatory follicle. The age of the donor affects success rates. When oocytes were collected from the follicles of young donors (6 to 10 years) and old donors (20 to 26 years) and transferred into the
oviducts of young recipients (3 to 7 years), significantly more oocytes from young than old donors developed 1130
into embryonic vesicles (11 of 12, 92%, versus 8 of 26, 31%, respectively).[10] A higher incidence of 1131
morphologic anomalies were observed in oocytes from old than from young mares.[11] Although younger mares are better candidates for oocyte donors, older (>20 years) mares frequently are presented to commercial oocyte transfer programs, and pregnancies are obtainable through repeated transfers.[2]

16.9.1.3 OOCYTE COLLECTION

Currently, most oocytes are collected from preovulatory follicles between 24 and 36 hours after the administration of human chorionic gonadotropin (hCG; 1500 to 2500 IU intravenously) to the donor (between 14 and 0 hours before anticipated ovulation, respectively). Therefore oocytes are probably at metaphase I or II. Criteria for hCG administration are (1) a follicle greater than 35 mm in diameter, (2) relaxed cervical and uterine tone, and (3) uterine edema or estrous behavior for a minimum of2 days. Some mares, especially old mares, do not consistently respond to hCG. In these cases, the authors use a

combination of gonadotropin-releasing hormone agonist (Ovuplant, deslorelin acetate, 2.1 mg subcutaneously) and hCG (2000 IU intravenously), with hCG administered between 4 and 5 hours after the gonadotropin-releasing hormone agonist. Oocytes have been collected from the follicles of mares using laparotomies,[12] colpotomies,[13] flank punctures,[14,15] and ultrasound-guided, follicular aspirations,[16,17] Currently, most laboratories collect oocytes through the flank or with ultrasound-guided punctures.

For the collection of oocytes using flank punctures, one places a trocar through the flank ipsilateral to the preovulatory follicle at approximately the position of the ovary. One manipulates the ovary per rectum to position the preovulatory follicle against the end of the cannula. While one stabilizes the ovary per rectum, one places a needle (12 to 17 gauge) through the cannula and into the follicular antrum and removes the follicular fluid and oocyte by gentle suction and lavage of the follicle. Transvaginal, ultrasound-guided follicular aspirations require use of an ultrasound machine. Linear, curvilinear, and sector transducers have been used. The transducer is placed in a casing containing a needle guide. Rectal contractions have been minimized through administration of propanthelene bromide (0.04 mg/kg intravenously)[2] or intrarectal use of lidocaine. One applies a nontoxic lubricant to the transducer and positions it within the anterior vagina lateral to the posterior cervix and ipsilateral to the follicle to be aspirated. One carefully positions the follicle through transrectal manipulations with the follicular apex juxtaposed to the needle guide and advances the needle through the needle guide to puncture the vaginal and follicular walls. In the authors' laboratory, a 12-gauge, double-lumen needle is used (Cook Veterinary Products, New Buffalo, Michigan). One aspirates the follicular fluid from the follicle usinga pump (Cook Veterinary Products) set at 150 mm Hg. After removal of follicular fluid, one lavages the lumen with between 50 and 100 ml of flush, typically modified Dulbecco's phosphate buffered solution or an embryo flush solution (EmCare, ICP, Auckland, New Zealand) containing fetal calf serum (1%) or bovine serum albumin (0.4%) and heparin (10 IU/ml). Oocytes were collected successfully from between 70% and 80% of the follicles in client donors.[2]

16.9.1.4 OOCYTE CULTURE AND TRANSFER

Oocytes are sensitive to temperature changes; therefore one should warm media and equipment for handlingthe oocyte to 38.5° C. On collection, one pours the flush into large search dishes and examines the flush under a dissecting microscope to locate the oocyte. One transfers oocytes collected 36 hours after hCG administration to the donor immediately into a recipient's oviduct. One cultures oocytes collected 24 hours after administration to the donor in vitro between 12 and 16 hours before transfer. Most oocytes are cultured in medium similar to that first described by Carnevale and Ginther.[10] The time of oocyte collection (24 versus 36 hours after administration of hCG to donors) did not affect pregnancy rates.[18] A modification of these procedures was to collect oocytes 24 hours after hCG and immediately transfer them into the recipient's oviduct. Oocyte maturation was completed within the oviduct, and recipients were inseminated after oocyte maturation should have been completed at 16 hours after transfer. Pregnancy rates were not statistically different for oocytes matured within the oviduct or within an incubator (43% versus 57%).[19]

Because the reproductive tract of the recipient provides the environment for sperm transport, fertilization, and embryo development, these mares should be young (optimally 4 to 10 years) and have normal reproductive tracts. Cyclic and noncyclic hormone-treated mares have been used as oocyte recipients. When cyclic mares are used, recipients are synchronized with the donor, and the recipient's own oocyte is removed by transvaginal or flank aspiration before transfer of the donor's oocytes.[20] Anestrus and early transitional mares were used as recipients during the nonovulatory season.[2,21] During the breeding season, a high dose of a gonadotropin-releasing hormone agonist (4.2 mg deslorelin acetate)[22] or injections of progesterone and

estrogen (150 mg progesterone and 10 mg estradiol)[3] have been administered to reduce follicular development in potential recipients. The endocrine environment of the cyclic mare is imitated in the noncyclic recipient with administration of estradiol (2 to 5 mg daily for 3 to 7 days) before transfer and progesterone (150 to 200 mg daily) after transfer. Pregnancies were maintained through the administration of exogenous progesterone or progestins.[2] 1131

1132

Because one transfers oocytes surgically, adequate exposure of the oviduct is essential, and mares with short, thick flanks or short, broad ligaments are not good candidates for recipients. Most oocyte transfers are performed through a standing flank laparotomy. Tranquilization, preparation, closure, and aftercare of recipients are similar to previously described methods for embryo transfer.[23] The authors generally use a fire-polished glass pipette to transfer oocytes. One locates the oviductal os by following the outline of the oviduct along the external surface of the infundibulum. One identifies the end of the structure and inserts the pipette containing the oocyte into the os and carefully advances the pipette 2to 3 cm. One deposits the oocyte and a minimal amountof medium (<0.1 ml) into the ampullar region of the oviduct, gently returns the ovary to the abdominal cavity, and closes the surgical site.

16.9.1.5 INSEMINATION OF RECIPIENTS

In a commercial oocyte transfer program, use of stallions with good fertility is essential for success; however, cooled, transported semen frequently is provided from different stallions of variable fertility.[2,24] The equine oocyte remains viable for approximately 12 hours after a natural ovulation.[25] Because of this limited life span, one must inseminate recipients before or directly after oocyte transfer or both. Pregnancies have occurred when recipients were inseminated only before[26,27] or after[19] the transfer of oocytes. However, for most experimental transfers, recipients were inseminated before transfer (approximately12 hours) and after transfer (approximately 2 hours) with a total of 2×10^9 motile sperm. In a commercial program using older donors and cooled semen from numerous stallions of variable fertility, pregnancy rates when recipients were inseminated before or before and after oocyte transfer were significantly higher than when recipients were inseminated only after transfer (18 of 45, 40%; 27 of 53, 51%; and 0 of 10, respectively).[24] The results suggest that insemination of a recipient only before transfer with at least 1×10^9 progressively motile sperm from a fertile stallion is sufficient. However, if fertility of the stallion is not optimal, insemination of the recipient before and after transfer could be beneficial.

After insemination and transfer, one examines the uterus of the recipient with ultrasound to detect intrauterine fluid collections. One treats recipients with intrauterine fluid collections as one treats ovulating mares, with oxytocin or prostaglandins to stimulate uterine contractions or with uterine lavage and infusion.

16.9.1.6 SUCCESS OF OOCYTE TRANSFER

Pregnancy rates for commercial transfers, using older donors and semen of variable quality, ranged from 27% to 40% per transfer.[2,24] In contrast, experimental transfers under similar conditions using oocytes from young mares and fertile stallions resulted in pregnancy rates between 54% and 83% per transfer.[24] However, one or more pregnancies were obtained for more than 80% of donors during the breeding season in a commercial oocyte transfer program.[2] All mares in the program had histories of reproductive failure in breeding and embryo transfer programs, with a mean of 7 years (range of 3 to 15 years) from the last successful pregnancy or embryo collection.[2]

16.9.1.7 IN VITRO MATURATION OF OOCYTES

Collection of oocytes from small follicles during diestrus results in significantly reduced collection rates compared with collection from preovulatory follicles.[28] In vitro fertilization is not repeatedly successful in the mare, with only two foals born after in vitro fertilization.[29,30] In a recent study,[26] oocytes were collected from small follicles and from preovulatory follicles. Oocytes collected from small follicles were matured in vitro for 36 to 38 hours before transfer, whereas oocytes collected from preovulatory follicles were transferred immediately into a recipient's oviduct. Embryo development rates after transfers were 9% for in vitro maturation and 82% for in vivo. In the past few years, a medium has been developed specifically for the equine oocyte,[31] and fertilization has been achieved by intracytoplasmic sperm injection (ICSI).[32,33] Research involving oocytes from excised ovaries is aimed at developing a method to salvage gametes from the ovaries of valuable mares that have died or have been euthanized. One can collect ovaries from mares immediately after death and ship them to a facility for oocyte recovery, maturation, and transfer. This technique was first attempted in 1999[2]; a pregnancy was established, which later underwent embryonic death. At this time, a late-term pregnancy has been established after shipment of ovaries from a mare that was euthanized for medical reasons.

16.9.1.8 CRYOPRESERVATION OF OOCYTESAND EMBRYOS

Cryopreservation of the equine oocyte results in the preservation of female genetics, whereas cryopreservation of the embryo results in the preservation of the female and male genome. The first foal was produced from a cryopreserved embryo in 1982.[34] Procedures for embryo cryopreservation have been reviewed.[35] Cryopreservation of small embryos (morulae or early blastocysts) has resulted consistently in acceptable pregnancy rates close to 50%.[36,37] Cryopreservation of larger embryos (>300 μm) is usually unsuccessful. Therefore embryo donors are examined twice daily for ovulation; and embryo collection is recommended on day 6 or 6½ after ovulation.[35] Although cryopreservation of the oocyte is difficult, 1132
successful fertilization of cryopreserved oocytes has been documented.[31,38,39] In 2001, the first foals were 1133
born after cryopreservation of oocytes.[27]

16.9.2 Assisted Reproductive Techniquesfor the Stallion

Maximum fertility was obtained when fertile mareswere inseminated every other day during estrus with500 × 10^6 progressively motile sperm.[40] Insemination of low numbers of sperm would be beneficial for frozen semen that is of limited supply, semen from subfertile stallions with low sperm numbers, and insemination of sex-sorted sperm. The following discussion summarizes current techniques for low-dose inseminations.

16.9.2.1 DEEP INTRAUTERINE INSEMINATION

Uterine contractions move sperm into the tips of the uterine horns within 20 minutes of routine artifical insemination.[41] The aim of deep uterine insemination is to increase the number of sperm entering the oviduct ipsilateral to ovulation.[42–44] One passes a flexible insemination pipette through the cervix and into the uterine horn ipsilateral to the preovulatory follicle. One then uses rectal manipulation to position the catheter at the tip of the uterine horn where the sperm are deposited. Fresh, cooled, and sex-sorted sperm in volumes

ranging from 0.2 to 1.0 ml of glucose milk extender have been used for deep intrauterine inseminations. Pregnancy rates after deep intrauterine inseminations with 5×10^6 progressively motile sperm were between 30% and 50%,[45,46] and inseminations with 25×10^6 progressively motile sperm ranged from 57% to 63%.[45,47] However, in the study by Woods, Rigby, Brinsko, et al.,[47] control mares were inseminated with 25×10^6 progressively motile sperm in the uterine body, and pregnancy rates were not significantly different between standard and deep uterine inseminations. Because control inseminations were not done in many studies, the true benefit of deep uterine insemination has not been determined.

16.9.2.2 HYSTEROSCOPIC INSEMINATION

Hysteroscopic insemination entails deposition of sperm directly onto the papilla of the uterotubal junction. A minute volume of extended sperm (approximately 0.05 to 0.25 ml) is desired for hysteroscopic insemination. Sperm are centrifuged through a density gradient to select a sperm population with a high percentage of motility. Numbers of fresh sperm that were inseminated ranged from 1 to 10×10^6 progressively motile sperm, with pregnancy rates from 40% to 75%.[46,48–50] Studies have been conducted using higher volumes[51] or lower sperm numbers[48]; however, fertility was reduced.

One aspirates semen into an equine gamete intrafallopian transfer (GIFT) catheter (Cook Veterinary Products) protected by an outer polypropylene cannula and loaded into the working channel of the videoendoscope. With a sterile gloved arm in the vagina of the mare the operator guides the flexible endoscope (1.6 m in length) through the cervix and uterine lumen; directs the endoscope along the uterine horn ipsilateral to the preovulatory follicle; and on imaging the papilla of the uterotubal junction, extrudes the outer cannula and then the inner GIFT catheter containing the sperm suspension from the working channel of the endoscope. When the tip of the GIFT catheter touches the papilla, the operator bubbles the inseminate onto the surface of the papilla.[48]

Low-dose insemination with frozen-thawed sperm maximizes the use of a conventional dose of frozen sperm (800 to 1000×10^6 progressively motile sperm) by reducing the number of sperm needed for insemination. Using 5 or 10×10^6 frozen-thawed progressively motile sperm, different investigators obtained pregnancy rates between 33% and 47%.[49,52,53] Alvarenga, Trinque, Lima, et al.[54] inseminated client mares with 100 to 150×10^6 frozen-thawed sperm from 15 Warmblood stallions and obtained an overall pregnancy rate of 57%, demonstrating that hysteroscopic insemination can be applied immediately in the horse industry. Current rates for sorting sperm into X or Y chromosome–bearing populationsare approximately 10 million sperm per hour, meaning that low-dose inseminations are necessary for sex-sorted sperm. Several studies have been conducted using hysteroscopic insemination of sex-sorted sperm, resulting in pregnancy rates between 25% and 44%.[49,52]

16.9.2.3 GAMETE INTRAFALLOPIAN TRANSFER

Gamete intrafallopian transfer involves transfer of oocytes and sperm into the recipient's oviduct. In comparison to oocyte transfer, GIFT requires low numbers of sperm. The first successful GIFT in the horse was reported in 1998.[21] After collection, one must centrifuge raw sperm through Percoll density gradient to select a population with high percentage of motile sperm, free of debris and seminal plasma. One places between 2 and 5×10^5 progressively motile sperm in medium containing the oocyte and places both gametes

into the oviduct of a recipient mare. Pregnancy rates obtained with GIFT ranged from 27% to 82%.[19,55] GIFT is a potentially valuable technique to produce pregnancies from subfertile stallions, frozen semen, and sex-sorted sperm. Recent studies in the authors' laboratory using cooled and frozen semen for GIFT resulted in pregnancy rates of 25% and 8%, respectively.[56]

16.9.2.4 METHODS FOR FERTILIZATION IN VITRO

Only two foals have been produced after in vitro fertilization of equine oocytes matured in vivo.[29,30] 1133
Increased fertilization rates have been observed following the application of ICSI in which one sperm is 1134
aspirated into a fine-bore needle and injected into a mature oocyte. The injected oocyte is activated and placed in culture to allow the completion of fertilization and cellular division in vitro. Squires, Wilson, Kato, et al.[57] reported the first successful ICSI of an equine oocyte that was maturedin vitro, and foals have been produced by ICSI using oocytes matured in vivo or in vitro.[58,59] However, pregnancy rates per transferred oocyte were low (13% and 6%, respectively). Recently, several investigators reported the in vitro production of blastocysts with higher efficiency,[32,60–62] increasing the expectations of establishing ICSI as a practical assisted reproductive technique for the horse.

16.10

16.10—The Stallion

Juan C. Samper

16.10.1

Anatomy and Physiologyof the Stallion

A breeding stallion is often the most significant financial asset of an equine breeding operation. A variety of factors may influence the future breeding potential of a colt as it is maturing. An understanding of the anatomy and physiology of the stallion assists a veterinarian in providing optimal monitoring, diagnostic, and therapeutic services to a farm.

16.10.1.1 REPRODUCTIVE PHYSIOLOGY

16.10.1.1.1 Testicular Descent

Normal testicular descent into the scrotum occurs between the last 30 days of gestation and the first 10 1135
days post partum. In some colts the testes may descend into the inguinal region and remain there for some 1136
time before fully descending. Androgen production by the developing fetal testis probably plays an important role,[1] as may mllerian inhibiting factor.[2] Traction of the gubernaculum, which attaches the caudal pole of the testis to the inguinal region, is believed to draw the developing testicle and epididymis into the inguinal ring.[3]

Failure of the testis to descend into a normal scrotal position is termed *cryptorchidism*. The left testis is retained more commonly in stallions. One diagnoses cryptorchidism by manual palpation of scrotal contents. Rectal palpation and careful inguinal palpation may assist in identification of an abdominally or inguinally retained testis. In some instances, heavy sedation of the stallionis necessary for one to examine the area carefully. Ultrasonography has been recommended as a useful diagnostic tool for such examinations as well.[4] In horses with bilaterally retained testicles or apparent geldings with stallionlike behavior, hormonal profiles maybe useful in diagnosis of a retained testis. Testosterone levels have been suggested as a method to diagnose retained testicular tissue in an apparent gelding. A stimulation test using human chorionic gonadotropin increases the chances of detecting testosterone. For this, one injects 5000to 10,000 IU of human chorionic gonadotropin intravenously. One determines testosterone concentrations before injection and 60 to 120 minutes later. A fivefold or greater increase in hormone indicates a retained testicle. However, false negatives are possible. A single measurement of blood estrone sulfate concentration is a reliable indicator of the presence of testicular tissue, especially in colts over 3 years of age.[5–7]

16.10.1.1.2 Puberty

Puberty is defined as the age at which a colt is able to mount, copulate, and successfully impregnate a mare and occurs during the second spring after the year of birth. Puberty should not be confused with sexual maturity, which occurs after the age of 5.

Puberty is probably regulated by the reactivationof the hypothalamic pulse generator, a group of cells located in the arcuate nucleus of the hypothalamus.[1] The pulsatile secretion of gonadotropin-releasing hormone (Gn-RH) from the hypothalamus stimulates the secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the anterior pituitary. Season, age, breed, nutritional status, and external hormones affect puberty, but in general puberty is complete by 18 to24 months in the horse.[8]

16.10.1.2 ENDOCRINOLOGY

The pineal gland plays a significant role in the seasonality of the horse. The retina captures photoperiod information and transports it via nerve fibers to the pineal gland, which in turn inhibits the production of melatonin during long days. Low levels of circulating melatonin are consistent with higher levels of Gn-RH and gonadotropins. Stallions, in contrast to mares, do not undergo a complete reproductive quiescence and

continue to produce sperm during the short photoperiodic days. The cause for this partial refractoriness of the stallion to changes in photoperiod is not well understood.

The hypothalamus, pituitary, and testes (hypothalamic-pituitary-gonadal axis) must work in synchrony fora stallion to be able to start and sustain sperm production. The primary role of the hypothalamus, locatedon the base of the brain, is the production of a10-amino-acid peptide known as Gn-RH, which is secreted in multiple daily pulses and then transported via the hypothalamic-pituitary portal system to the anterior pituitary. In addition to melatonin-mediated stimulus, the hypothalamus responds to tactile, olfactory, and visual stimuli.[9]

The pituitary, which is connected to the hypothalamus by neural fibers, has two lobes. The anterior lobe possesses Gn-RH receptors. Gonadotropin-releasing hormone binds to these receptors and induces secretion of FSH or LH. The anterior pituitary also produces prolactin, the role of which is unclear in the stallion. Follicle-stimulating hormone and LH act on the Sertoli's and Leydig's cells, respectively, stimulating production of steroids and other protein hormones. The peptide hormones inhibin and activin regulate FSH at the pituitary level. Testicular steroid hormones, mainly estradiol and testosterone, in turn have positive or negative feedback actions at the level of the pituitary on FSH and LH, respectively.

The complexity of the interaction between hormones has precluded clinicians and researchers in the field of stallion andrology from being able to develop a test or a series of hormonal tests to predict or diagnose infertility or subfertility. Until such diagnostic methods become available, hormonal supplementation is strictly empirical and potentially can worsen or elicit a reproductive dysfunction in otherwise normal stallions.[9]

16.10.1.3 TESTICULAR CELLS

The endocrine role of the testes is to produce testosterone and estrone sulfate, whereas the exocrine role is to produce spermatozoa. The testicle is composed of 85% to 90% testicular parenchyma, of which seminiferous tubules comprise 70%. In turn the seminiferous tubules are formed by Sertoli's and germinal cells. The interstitium, formed primarily by Leydig's cells and myoid cells, occupies close to 15% of the parenchyma.[10]

16.10.1.3.1 Sertoli's Cells

Sertoli's cells, also known as supportive cells, contain the most testicular receptors for FSH. Some of the 1136
most important functions of the Sertoli's cell in the process of sperm maturation include the following: 1137

1. Isolation of the advanced (haploid) stages of spermatogenesis by tight gap junctions forming the blood-testis barrier.

2. Production of androgen binding protein, activin, and inhibin. Androgen binding protein binds the bioactive form of testosterone, dihydrotestosterone, to maintain high levels of these products in the seminiferous tubules and epididymis. Activin and inhibin stimulate or suppress the release of FSH from the pituitary. The Sertoli's cells contribute to the regulation of Leydig's cell function and establish feedback mechanisms to the anterior pituitary primarily through the production of activin and inhibin. Sertoli's cells synthesize other proteins, such as SGP-2, ceruloplasmin, and transferrin, that are necessary to support spermatogenesis. Ceruloplasmin and transferrin act as carrier proteins for copper and iron, respectively, which are important regulators of spermatogenesis.

3. Germ cells begin the process of differentiation as large round cells on the basal compartment of the seminiferous tubule and approximately 55 days later finish as elongated cells in an adluminal position. This change in size, shape, and position occurs between two adjacent Sertoli's cells. The number of spermatogenic cells and ultimately the total sperm production of a given stallion are determined by the number of cells that can be accommodated between the tight gap junctions between two Sertoli's cells. Day length appears to be one of the most important factors in determining the number of Sertoli's cells per testis in adult stallions. Numbers of Sertoli's cells increase in young animals:1 billion cells at 2 years of age, 2.8 billion at 3 years, and 3.6 billion after 4 to 5 years of age. The number of Sertoli's cells then decreases with advancing age.[11]

16.10.1.3.2
Leydig's Cells

The interstitial or Leydig's cells contain most of the testicular receptors for LH and are the main site of testosterone production. Testosterone concentration in the testicular microcirculation is at least 10 times higher than that in the general circulation. Through steroid production, Leydig's cells provide the feedback mechanisms on the pituitary necessary to maintain spermatogenesis, secondary sex characteristics, and libido. Season and not age appear to affect the testosterone production in adult stallions, which is mediated through a changein total number of Leydig's cells rather than totalvolume of cells per testis. Unlike Sertoli's cells, Leydig'scell numbers do not increase dramatically with age(1.4 billion at 2 years and 4.7 billion as a mature stallion). However, a significant increase in cell volume occurs that is regulated primarily by season.[12]

16.10.1.3.3
Myoid Cells

The myoid cell has profound effects on germ cells and Leydig's cells primarily through the action of paracrine modulating factors. A paracrine modulating factor in the rat known as P-Mod-S is thought to stimulate or modulate some of the androgen binding protein functions. In addition, the myoid cells are responsible for the round architecture of the seminiferous tubule and probably for the intratesticular movement of sperm.

16.10.1.3.4
Germinal Cells

Sperm is the final product of a 57-day process that starts at the base of the seminiferous tubule. In a normal stallion, testicular volume has a direct correlation with the number of sperm that particular animal should be able to produce.[13]

16.10.1.4
SPERMATOGENESIS

Spermatogenesis is the series of chronologic changes that occur in the seminiferous tubule, transforming a large, round spermatogonia into a spermatozoa. This process in the stallion takes approximately 57 days and is not affected by frequency of ejaculation or season.[14]

The process starts when an A_1 stem cell spermatogonia undergoes mitosis giving rise to (1) a second A_1 spermatogonia to maintain a constant population of stem cells and (2) an A_2 spermatogonia. In turn, the A_2 spermatogonia gives rise to A_3, A_3 to B_1, and B_1 to B_2. The entire process of spermatogenesis has been

divided into three phases of similar length known as spermatocytogenesis, meiotic divisions, and spermiogenesis. *Spermatocytogenesis* is characterized by the mitotic divisions ofA and B spermatogonia. *Meiotic divisions* result in the formation of primary spermatocytes from B_2 spermatogonia and the subsequent formation of secondary spermatids. Leptotene spermatocytes that form immediately after the first meiotic division are hidden from the immune system by the hematotesticular barrier. *Spermiogenesis* is characterized by the transformation of round spermatogonia to elongated spermatids and ultimately to spermatozoa. During spermiogenesis, the formation of the acrosome arises from the Golgi complex and the compaction of DNA, partly because of the expression of protamine genes at the spermatid stage. The end of spermatogenesis is characterized by *spermiation*, the release of the elongated spermatids or spermatozoa into the lumen of the seminiferous tubule.[15]

16.10.1.5 SEASONALITY

Although a reduction in testicular size, testicular volume, and daily sperm production during the non–breeding season occur, the seasonal effect varies significantly between stallions and is not as significant as 1137
the effect on ovarian function in the mare. Stallions from which semen is collected year-round decrease their 1138
sperm output on the average by 1 to 2 billion during the non–breeding season. In many of these stallions libido is not affected adversely. Although the total number of sperm is affected, sperm morphology and motility remain unaltered, provided stallions are maintained on a regular collection schedule. The effect of day length on sperm production can be explained by a decrease in serum LH during the non–breeding season. This lack of stimulus to the Leydig's cell has a direct effect on intra- and extratesticular testosterone levels. Decreased testosterone concentration affects the number of Sertoli's cells and in turn the total number of germ cells that can be allocated between two Sertoli's cells.[16]

The effect of external lighting programs on spermatogenesis is uncertain. Burns and Douglas[16a] reported increased sperm production and testicular size in stallions subjected to a lighting program but observed that this improvement was transitory, and in some cases detrimental, to stallion performance at the peak of the breeding season (April to May). Other investigators have foundno detrimental effect on photostimulated stallions.[16,17] Several Thoroughbred breeding farms provide lightto their stallions before the breeding season without significant reduction in conception rates.

16.10.1.6 TESTICULAR CELL INTERACTIONS

A well-established fact is that the Sertoli's or nursecells have a direct interaction with the germ cells andthat Leydig's cells interact with Sertoli's and germinal cells through hormonal production. In addition, the myoid cell produces at least one paracrine factor that interacts directly with the Sertoli's cell. Paracrine and autocrine modulating factors, products of the peritubular cell, appear to have an effect on androgen binding protein function. In turn, the myoid cell is under regulatory influence of transforming growth factorsα (stimulatory) and β (inhibitory). Other factors involved in cell-to-cell communication of the testicular cells include collagen, plasminogen activator, vitamin A, pyruvate, and carbohydrates.[18] Most of these products and mechanisms have not been investigated extensively in the stallion.

16.10.1.7 EPIDIDYMIS

The specific absorptive and secretory functions of each segment of the stallion epididymis remains the subject of considerable debate and investigation. The histologic structure of the epididymis changes as it

continues through its different regions, with epithelial height being greatest proximally and smooth muscle components greatest distally.[19] As spermatozoa are transported from the excurrent ducts into the head, along the body, and into the tail, they undergo a number of morphologic and physiologic changes that ultimately render them motile and fertile. Specific maturational changes include (1) the capacity for progressive motility, (2) shedding of the cytoplasmic droplet, (3) plasma and acrosomal membrane alterations, (4) DNA stabilization, and (5) metabolic changes.[20] The tail of the epididymis generally serves to store the matured spermatozoa. All of these changes occur primarily at the level of the mid to distal corpus.[20,21]

Throughout the epididymis, fluid resorption occurs at a steady rate and results in a significant increase in sperm concentration.[22] Whether stallions with high-volume ejaculates and poor sperm morphology have epidydimal dysfunction remains to be investigated.

16.10.1.8 EXTERNAL GENITALIA

16.10.1.8.1 Penis and Prepuce

The penis of the stallion is composed of a root, a body, and a glans penis and is musculocavernous. The penile base arises at the ischial arch in the form of two crura that fuse distally to form the single dorsal corpus cavernosum penis enclosed by a thick tunica albuginea. The corpus cavernosum, corpus spongiosum, and corpus spongiosum glandis are the three spaces that make up the erectile tissue of the penis. Engorgement of these spaces with blood from branches of the internal and external pudendal arteries and obturator arteries is responsible for erection. The cavernous spaces within the penis are continuous with the veins responsible for drainage. The corpus spongiosum originates in the pelvic area and surrounds the penile urethra within a groove on the ventral side of the penis and forms the corpus spongiosum glandis at the distal end of the penis.[23] The corpus spongiosum glandis is responsible for the distinct bell shape of the stallion penis following ejaculation.

The urethral process is distinctly visible at the center of the glans penis and is surrounded by an invagination known as the fossa glandis. Accumulations of smegma secretions, known as “beans,” are predisposed in one or all of the diverticulae of the fossa glandis and urethral sinus. Careful examination and cleaning of this area are imperative during the reproductive evaluation of a stallion or before breeding.

The bulbospongiosus muscle located in the ventral aspect of the penis provides rhythmic contractions or pulsations to assist in moving the penile urethral contents (semen and urine) distally during ejaculation. Two retractor penis muscles also run ventrally along the length of the penis and are responsible for returning the penis to the sheath following detumescence.[24]

The prepuce is formed by a double fold of skin thatis hairless and well supplied with sebaceous and sweat glands. The prepuce functions to contain and protectthe nonerect penis. The external part of the prepuce, or 1138
sheath, begins at the scrotum and displays raphae that are continuous with the scrotal raphae. The internal 1139
layer of the prepuce extends caudally from the orifice to line the internal side of the sheath and then reflects cranially toward the orifice again before reflecting caudally to form the internal preputial fold and preputial ring. This additional internal fold allows the considerable lengthening (approximately 50%) of the penis during erection. During erection the preputial orifice is visible at the base of the penis just in front of the scrotum, and the preputial ring is visible approximately midshaft of the penis.[24]

One can best examine the penis and prepuce of a breeding stallion following teasing with an estrous mare, when one can observe the stallion drop the penis and attain a full erection.[25] The prepuce and penis shouldbe free of vesicular, proliferative, or inflammatory lesions such as those found in cases of coital exanthema, squamous cell carcinoma, or cutaneous habronemiasis. Removal of smegma accumulations may be required for a complete examination of the skin surfaces.

16.10.1.8.2 Scrotum

The scrotum is slightly pendulous and forms two distinct pouches that contain, protect, and thermoregulate the testes and epididymides. The testes are located in the scrotum to maintain testicular temperature at 3° to 5° C below the normal body temperature, which is a requirement for normal spermatogenesis.[26]

The scrotal wall consists of four layers: the skin, tunica dartos, scrotal fascia, and parietal vaginal tunic.[22,27] The scrotal skin is thin, generally hairless, and slightly oily, containing numerous sebaceous and sweat glands that assist in thermoregulation. The tunica dartos adheres to the scrotal skin and consists of muscular and fibroelastic tissue. The tunica dartos lines both scrotal pouches and extends into the median septum, which appears externally as the median rapha of the scrotum. The scrotal fascia is between the tunica dartos and parietal vaginal tunic and allows the testis and associated parietal tunic layer to move freely within the scrotum. The parietal vaginal tunic is the innermost layer and is an evagination of the parietal peritoneum through the inguinal rings that forms during testicular descent. This layer forms a sac that lines the scrotum and is apposed closely to the visceral vaginal tunic, the outer layer of the testis itself. The vaginal cavity isthe space between the parietal and visceral layers of the vaginal tunic and normally contains a small amount of viscous fluid to allow some free movement of the testis within. The vaginal cavity is a potential space within which considerable fluid may accumulate.

The scrotum of the normal stallion should appear slightly pendulous, globular, and generally symmetric. One may observe normal variations in the positioningof the testes if one testis is anterior to or ventral tothe other. The skin should have no evidence of trauma, scarring, or skin lesions. Palpation of the scrotum of a normal stallion reveals a thin and pliable covering that slides loosely and easily over the testicles and epididymides within.

16.10.1.8.3 Testicles

The testes of a normal stallion are palpable as two oval structures of nearly equal size lying horizontally within the scrotal pouches. One ascertains normal orientation of the testis by palpation of the body of the epididymis, which is always dorsolateral to the testicle proper, and the tail of the epididymis and the ligament of the tailof the epididymis, which should be in a caudal position. The ligament is palpable as a fibrous nodule 5 to 19 mm in size that attaches the tail of the epididymis to the caudal pole of the testis. The ligament is particularly large in newborn colts and on palpation may be mistaken for a testis within the scrotum. Examination of a normal stallion may identify rotation of one or both testes, upto 180 degrees. Such rotations can be permanent, or the testis may rotate back and forth, usually with the stallion showing no outward signs of discomfort. A rotated testicle may have as much as a 40% reduction in blood flow.[26] Although this condition does not interfere with normal breeding by the stallion, it may be considered a criterion for failing a stallion during a breeding soundness examination in some breed regulations. One should note the presence of the condition clearly on the record of the stallion and communicate such

clearly to the owner. One must differentiate testis rotation from true testicular torsion in which stallions demonstrate signsof colic and for which palpation reveals a painful and swollen testicle.

Within the scrotum the testis is encapsulated by the tunica albuginea, a layer of tough collagenous tissue and smooth muscle that sends supportive trabeculae into the testicular parenchyma, dividing the testis into lobules. The muscular content of the tunica albuginea is thought to play a role in intratesticular sperm transport and determination of testicular tone.[22]

Testicular tone is described as the degree of turgidity of the testicle, which should be firm to turgid but resilient on palpation. Deviation from the normal toward a softer or firmer testis may be associated with degenerative, neoplastic, or traumatic conditions of the testis. Testicular degeneration is an acquired reversible or irreversible condition in which damage to the germinal epithelium results in eventual atrophy of the epithelium and an initial loss of testicular tone. As the disease progresses, the degenerating testicle becomes small and firm as fibrous tissue replaces testicular parenchyma. Because testicular conditions 1139
may afflict only one testis, comparison of the size and consistency of the two testes of any individual 1140
stallion is imperative. One can determine changes in testicular tone or consistency best by sequential examinations of the stallion that allow the clinician to monitor the severity and rate of change as the disease progresses. Regular physical examinations of breeding stallions are an important part of routine stallion management and may allow early detection of problems that may affect fertility.

16.10.1.8.4 Testicular Size and Volume

Testicular size in stallions increases from the pubertal period to reach maximal size at the age of 5 to 6 years and is affected by breed, season, and age. Each testisof an adult stallion weighs between 150 and 300 g and measures 50 to 80 mm in width, 60 to 70 mm in height, and 80 to 140 mm in length, with breed being the biggest factor in determining size. Testicular volume correlates highly with daily sperm production and therefore is a useful predictor of the sperm production potential of a stallion.[28]

To calculate the testicular volume, one should obtain measurements of the length, width, and height of each testicle by calipers or ultrasound. Ultrasonographic measurements may be more accurate, although proper placement of the probe across the testis to ensure one obtains a cross-sectional image is critical. Because a testis approximates the shape of an ellipsoid, the following formula converts length, width, and height measurements into testicular volume:

$$\text{Testis volume} = \tfrac{4}{3}\pi(\text{length}/2)(\text{width}/2)(\text{height}/2)$$

or,

$$\text{Testis volume} = 0.5333 \times H \times L \times W$$

Love, Garcia, Riera, et al.[28] also recommend using this volume to predict the expected daily sperm output (DSO) of the stallion, using the following formula:

$$\text{Predicted DSO} = [0.024 \times (\text{volume of left} + \text{volume of right})] - 0.76$$

One can compare predicted daily sperm output with actual daily sperm output as estimated by semen collection during the routine breeding soundness examination. A stallion in which actual daily sperm

output falls below that predicted for his testicular size requires further evaluation for disease conditions of the testes, epididymides, and accessory glands.

Testicular measurements are a useful and important part of the physical examination of any breeding stallion and can be used to predict sperm output and determine the size of the book for a given stallion. A stallion with small testicles will have lower sperm production and may need modification of the management strategies that result in optimization of the fertility of such a stallion.

16.10.1.8.5 Epididymides and Excurrent Duct System

The epididymis is a single, highly convoluted duct approximately 70 m in length that has a grossly distinct head, body, and tail. The head of the epididymis is a flattened structure that lies dorsomedially along the cranial border of the testis and is attached closely to the testis. The body, or corpus, lies along the dorsolateral aspect of each testis and continues as the tail, or cauda, the large, prominent structure attached to the caudal pole of the testis. The deferent duct, the excretory duct for sperm, attaches to the tail of the corresponding epididymis, runs along the medial aspect of the testis, and ascends via the spermatic cord through the vaginal ring into the pelvis. Each deferent duct widens into its corresponding ampullary region and eventually terminates at the colliculus seminalis of the pelvic urethra. The colliculus seminalis is a rounded prominence situated on the dorsomedial wall of the urethra about 5 cm caudal to the urethral opening from the bladder. The colliculus is the common opening to the ampullae and the seminal vesicles. With care one can palpate all sections of the epididymis through the scrotal wall. However, the head of the epididymis may be difficult to ascertain because of its flattened nature and the close apposition of the cremaster muscle overlying it.[29]

16.10.1.8.6 Spermatic Cord

Each spermatic cord is enveloped in the parietal layer of the vaginal tunic, which extends distally from the internal inguinal ring. Within each cord are the corresponding deferent duct, testicular artery, testicular veins, lymphatic vessels, and nerves. The cremaster muscle is situated in the caudolateral borders of each spermatic cord. The testicular artery, a branch of the abdominal aorta, descends through the inguinal ring into the cranial border of the spermatic cord in a tortuous manner and divides near the testis into several branches to supply the testis and epididymis. These small branches, embedded in the tunica albuginea, enter the parenchyma via the trabeculae and septae of the testis. A corresponding network of veins leaves the testis and surrounds the testicular artery in a tortuous manner, forming the pampiniform plexus. This arrangement of artery and veins is responsible for much of the thermoregulation of the testis in the stallion when heat from the testicular arterial blood is transferred to the venous side, resulting in testicular arterial blood being several degrees cooler than systemic blood temperature. Abnormal distention of the veins of the pampiniform plexus is termed a *varicocele* and is an uncommon condition in stallions. Palpation of the spermatic cord of an affected stallion reveals the dilated and often tortuous vessels. Varicoceles are usually not painful but can result in fluid accumulation around the vaginal tunics, most often involve only one side 1140
of the spermatic cord, and most often can diagnosed by the observation of the dilation of the vessels from 1141
the pampiniform plexus with ultrasonography. The condition has been identified in stallions with normal semen parameters.[29]

16.10.1.8.7 Ultrasonographic Examinationof the Testicles and Epididymis

Ultrasound examination of the testis and epididymis is a useful ancillary diagnostic tool that enables the clinician to assess palpable changes and to identify nonpalpable changes. Ultrasound is particularly useful in cases of generalized scrotal enlargement in which specific structures become difficult to palpate.

Examination is usually easier following semen collection when the stallion is relaxed. One uses a 5.0-, 7.5-, or 10.0-MHz linear array transducer.[30] One usually beings the examination at the cranial end of the testis and slowly moves the probe caudally in a vertical position. Visualization of the scrotum reveals a thin, echogenic, uniform layer. Minimal, if any fluid is visible between the scrotal skin and testicular parenchyma in the normal stallion. In the cranial third of the scrotum, the head of the epididymis, testicular parenchyma, blood vessels of the spermatic cord, and central vein are visible. As one moves the probe caudally, the central vein and spermatic cord vessels disappear and the head of the epididymis continues into the body of the epididymis. The head and body of the epididymis appear as heterogeneous areas just below the spermatic cord when the probe is positioned as described. As the probe continues further caudally, the body ofthe epididymis becomes indistinct.[31] With the exceptionof the central vein, the testicular parenchyma appears uniformly echogenic and homogenous. The central vein appears as a small anechoic area within the testicular parenchyma at the cranial third of the testis and should not be mistaken for a pathologic lesion. Dilation of the central vein may be visible in cases of varicocele or spermatic cord torsions and usually is accompanied by detectable dilations of the vessels of the spermatic cord. Well-defined and hypoechoic lesions within the parenchyma suggest testicular tumors.

When one reaches the most caudal aspect of the testis, one rotates the probe to face cranially in a vertical position to allow examination of the tail of the epididymis. This structure appears as a heterogeneous area, described as having a Swiss cheese–like appearance. Identification of the epididymal tail may assist in diagnosis of testicular rotations. In cases of 360-degree torsions, the tail of the epididymis, although in its caudal position, is more dorsal because of the tension on the ligament of the tail of the epididymis by the deferent duct.

One can visualize the spermatic cord most easilyby placing the probe horizontally across the cord, just proximal to the body of the testis. The arrangementof the pampiniform plexus results in the mottled, heterogeneous appearance of the spermatic cord, and the testicular artery and veins are identifiable in cross-sectional images.[31]

16.10.1.9 INTERNAL GENITALIA

16.10.1.9.1 Accesory Sex Glands

The bulbourethral glands, prostate gland, and seminal vesicles collectively are referred to as the accessory sex glands. Their secretions produce the seminal plasma that comprises most of the ejaculate volume. The ampullae, which are dilations of the vas deferens before openingin the colliculus seminalis, are considered a storage place for sperm.

Although a short exposure to seminal plasma appears to be important for sperm function, long-term exposure to seminal plasma components may be detrimental to spermatozoa survival for some stallions. Artificial insemination programs deal with this potential detrimental effect by dilution of semen with

extenders in fresh or fresh-chilled programs and by centrifugation to remove seminal plasma in frozen semen programs and some chilled-shipped programs. Seminal plasma appears to suppress the inflammatory response of the endometrium of the mare to sperm following insemination or natural mating. Although the functions of the specific components of the seminal plasma remain rather obscure, the fluid suspends the ejaculated sperm and also is thought to be a source of energy, protein, and other macromolecules required for sperm functions and metabolism.[32–34]

16.10.1.9.2 Examination and Ultrasonographyof the Accessory Sex Glands

In some cases the reproductive examination of stallions should include rectal palpation and ultrasonography of the accessory sex glands.[35,36] Most stallions tolerate this procedure well with adequate restraint in stocks, and tranquilization is not usually necessary. Glands on sexually stimulated stallions are easier to palpate and to visualize.

16.10.1.9.3 Bulbourethral Glands

The bulbourethral glands, although not usually palpable per rectum because of the urethralis and bulboglandularis muscles close to the ischiatic arch, are easy to evaluateby ultrasonography. Multiple ductules from the bulbourethral glands enter the medial aspect of the urethra distal to the prostatic ductules. Bulbourethral gland secretions comprise most of the presperm or first fraction of the ejaculate and serve as a cleanser and pH stabilizer in the urethra before ejaculation. Using ultrasonography, one locates the bulbourethral glands 3 to 4 cm insidethe anus off the midline, and in a stimulated stallion, the 1141
glands appear as two distinct ovoid structures with multiple small hypoechoic spaces throughout the 1142
parenchyma.[35]

16.10.1.9.4 Prostate Gland

In the stallion the prostate is formed by a central isthmus and two lateral lobes located on the caudolateral borders of each vesicular gland. Although not always palpable per rectum, the prostate is lobulated or nodular and firm, distinguishing it from the smooth, thin-walled vesicular glands lying next to it. Each prostatic lobe measures5 to 9 cm long, 2 to 6 cm wide, and 1 to 2 cm thick. Multiple ductules from the prostate enter the lumen of the urethra lateral to the colliculus seminalis. The secretions of the prostate contribute to the sperm-rich fraction of the ejaculate. The lobes of the prostate are easily identifiable with ultrasonography with the two symmetric and homogeneously echogenic lobes distinctly visible lateral to the area in which the penile urethra merges with the neck of the bladder. Hypoechoic dilations within the gland parenchyma of each lobe are evidentin a teased stallion.[35]

16.10.1.9.5 Ampullae

The ampullae are the enlarged distal portions of the deferent ducts measuring 1 to 2 cm in diameter and 10 to 25 cm in length. Palpable along the midline of the pelvic floor over the neck of the bladder, they converge caudally and pass beneath the prostate gland but lie dorsal to the pelvic urethra. At their distal ends they continue through the wall of the urethra, opening into the colliculus seminalis alongside the excretory ducts of the seminal vesicles. The ampullae, in addition to serving as a sperm storage area, have many branched tubular glands located within the thickened wall.[36]

Because of the longitudinal orientation of the ampullae, sometimes they are easier to find on rectal palpation. One can identify them by ultrasonography by their hypoechoic central lumen surrounded by a uniformly echogenic wall and a hyperechogenic outer muscular layer. Orienting the transducer in a transverse position inside the rectum can provide a good cross-sectional image of the ampullae. The ampullae can be a common site for blockage because of sperm stasis. In these cases, dilation of the lumen may or may not be visible. Stallions with such blockage usually have a history of infertility or subfertility and often display severe oligospermia or, in severe cases, complete azoospermia. When sperm are present, they have a variety of morphologic abnormalities with predominantly tailless heads; in some instances the ampullae are palpably enlarged. This condition may render a stallion virtually infertile if undiagnosed. Recommendations for treatment include ampullary massage per rectum and repeated daily semen collection following injection of low doses of oxytocin or prostaglandin.[37]

16.10.1.9.6 Seminal Vesicles

The seminal vesicles or vesicular glands are paired, pyriform, and thin-walled structures lying lateral to the ampullae. On occasion, they may extend far craniallyto hang over the brim of the pelvis. Sexual stimulation results in dilation and elongation of the vesicularglands, up to 12 to 20 cm long and 5 cm in diameter. The distal ends of the glands converge, passing under the prostate as they lie parallel the ampullae toward their termination at the urethra. The excurrent ducts of the vesicular glands open lateral to the excurrent ducts ofthe ampullae at the colliculus seminalis of the urethra. Secretions of the vesicular glands comprise the gel fraction of the ejaculate. Higher gel volumes are collectable with pronounced sexual stimulation and season. The specific function of the gel fraction is unclear, and one should remove it when processing semen for evaluation or artificial insemination. Palpation of the vesicular glands may be easier following considerable teasing of the stallion with an estrous mare. The glands also are readily palpable in instances of pathologic enlargement.

With ultrasonography the vesicular glands appear in longitudinal section as flattened oval to triangular sacs, depending on the degree of sexual stimulation. A thin echogenic wall surrounds a generally uniformly anechoic lumen.[35] Increased echogenicity of vesicular gland fluid is associated with the highly viscous gel fraction produced by some stallions. The seminal vesicles are the glands that are most prone to bacterial infections. Diagnosis is based on the cytologic evaluation of the semen with presence of white blood cells.

16.10.1.9.7 Evaluation of the Pelvic and Penile Urethra

Although one can evaluate the pelvic urethra by transrectal ultrasonography, in most cases such evaluation is unrewarding. Endoscopic examination provides better information of the anatomic integrity of the urethra and its accessory structures. One performs the procedure by gently passing a 1-m endoscope with an outer diameter of 8 to 9 mm into the urethra of a sedated horse, so that the penis is relaxed. One applies gentle and constant pressure so as to pass 70 to 80 cm of the endoscope into the urethra.[38,39] One must take care not to inflate the bladder with too much air because of a slight risk of rupturing the bladder.

The bulbourethral gland ductules are grouped about 2.5 to 3 cm distal to the prostatic openings and are visible as two rows of 6 to 10 small openings dorsal and close to the midline. The prostatic ductules are arranged in a similar way to the bulbourethral and visible as two groups of small openings lateral to the ejaculatory orifices about 5 cm deeper. Just ventral and cranial to the colliculus, the openings of the 1142

urethral glands are visible laterally on the widened pelvic portion of the urethra, at the level of the prostatic gland openings.[38] 1143

One can identify the colliculus seminalis as a rounded prominent structure found on the medial aspect of the dorsal wall of the urethra approximately 5 cm caudal to the internal opening of the urethra from the bladder. On either side of the colliculus is an ejaculatory duct orifice, a small slitlike diverticulum within which the ampullary ducts and ducts of the seminal vesicle open. By passing the endoscope into this orifice, one can visualize and evaluate the seminal vesicles.[38,39] One can take samples for culture with endoscopic culturettes if one suspects seminal vesiculitis.[40]

Endoscopic examination of the urethra is indicated in cases of hemospermia or in cases in which one suspects a pathologic condition of the accessory sex gland. In cases of hemospermia, one may visualize the bleeding area with the endoscope. One can identify these lesions most readily in the region of the ischiatic arch and distal urethra. One should take care to assess the urethral mucosa as the endoscope is passed forward, because some irritation and erythema of the mucosal lining often results from the endoscopic examination.[40] A false diagnosis of urethritis may result if one assesses the mucosa while withdrawing the endoscope.

16.10.2 Evaluation of the Breeding Stallion

Equids in the wild are considered to be long-day seasonal breeders that live in a stable social group or harem. Free-running stallions interact with a female for hours or even days before copulation. In many management situations the domesticated stallion is restricted severely from its sociosexual activity. In general, breeding stallions are confined to a paddock or a box stall and do not have social interactions with other horses. In addition, mating and/or ejaculation often is permitted only under two conditions: *Hand mating* at the convenience of the farm manager, allowing only a few minutes for stallion and mare interaction, or *mounting of a mare or a phantom* for artificial insemination purposes.

Perhaps the most remarkable difference in the breeding pattern, particularly with performance horses such as Thoroughbreds and Standardbreds, is the fact that most breedings are done during February to June, well in advance of the natural breeding season (May to September).

16.10.2.1 BEHAVIOR

16.10.2.1.1 Normal Behavior

Stallions display several behavioral responses during teasing and breeding. However, the intensity of the response, also known as *libido*, and the type of response depend greatly on breeding experience, management, and in some cases, season. Olfactory, visual, and auditory stimuli also influence libido. Typically, a normal stallion that has never bred a mare takes a longer time to mount but displays good libido. However, a stallion that has had a negative previous experience might show no interestin the mare or in mounting. Some of the typical normal responses by stallions when exposed to an estrous mare include vocalization, flehmen response, striking, nipping/biting, and sniffing/licking. A normal stallion should show interest in the mare and drop the penis within 1 to 2 minutes of exposure to a quiet mare in standing heat and should try to mount within the first 3 minutes. Once stallions are allowed to mount, they give several (fiveto eight) intravaginal thrusts, followed by three to five short thrusts immediately before

ejaculation. Signs of ejaculation are rhythmic and frequent urethral pulsation, flagging of the tail, and a head relaxation. A single stallion tends to be consistent in its breeding behavior, provided that the conditions under which he usually breeds are the same.[41]

16.10.2.1.2
Abnormal Behavior

Stallion behavioral dysfunction in many instances is difficult to define and is relative to the expectations of the breeding manager. A stallion that takes 30 minutes or more to mount and ejaculate or takes several mounts may be considered a problem in some intensive management situations. However, a stallion that takes several hours to achieve an erection, mount, and ejaculate may be considered normal if he only breeds two or three mares during the entire breeding season in pasture conditions.

A review of the incidence of problems in 250 stallions over a period of 5 years indicated that more than 50% of the cases had complaints related to poor libido or excessive aggressiveness. Of those, nearly half were described in stallions with no previous sexual experience. The rest were divided evenly between experienced stallions with low sexual interest and unruly and overly aggressive breeders. Mounting and erection dysfunction accountedfor 11% of complaints, whereas ejaculatory problems accounted for 25% of the total cases. Other problems, such as self-mutilation and severe stereotypies that reportedly could be detrimental to fertility, accounted for 11% of the reported cases.[42]

16.10.2.1.3
Diagnosis of Abnormal Behavior

A normal stallion exposed to a mare in standing estrus should vocalize, sniff or nuzzle the mare, display the flehmen response by curling his upper lip, drop his penis, and achieve an erection within the first 3 minutes after initial exposure.[43] These precopulatory responses should be followed by mounting, 1143
intromission, and ejaculation. A normal, experienced stallion that is hand bred should require no more than 1144
5 minutes from initial exposure to a mare until ejaculation. The frequency and intensity of the precopulatory responses is affected by management, breeding experience, and external stimuli. Stallions with no previous breeding experience are expected to be slower in mounting. However, interest in the mare and time to erection should be within normal limits. Once the novice stallion mounts, he soon gains confidence and ejaculation should occur following a normal thrusting pattern. After the first positive experience, time to mounting and to ejaculation should decrease. One must treat novice stallions with patience, positive reinforcement, and perseverance. During this time, unnecessary punishment and rough handling can aggravate a problem and may result in profound breeding disinterest. One should investigate any aberration in courtship or copulatory behavior carefully, always keeping in mind that sexual behavioral dysfunction is a problem with many possible causes involving management and the endocrine, cardiovascular, musculoskeletal, and nervous systems.[44]

16.10.2.1.4
Lack of Libido

Libido, defined as sexual drive or interest in breeding, is high in most stallions. Sexual stimuli and environmental factors profoundly affect libido in stallions. One may observe low libido in improperly stimulated stallions. The best stimulus is a mare in standing heat. If this is not possible, one may use an estrogenized ovariectomized mare. Some stallions might have preference or aversion for a particular color or type of mare.[44] Experienced stallions frequently are aroused by exposure to a breeding phantom. One

should not expect a novice stallion or one that has never mounted a breeding phantom to be stimulated positively by a dummy.

One may observe lack of libido in experienced stallions toward the end of the breeding season, particularly in heavily used or overused animals. One can correct this problem easily by decreasing the frequency of service or collection.

Stallions that have been kicked by mares or negatively reinforced for displaying sexual behavior in shows or while performing at the track may have reduced sexual desire. Unfortunately, circulating levels of steroids or gonadotrophins are often poor predictors of libido.

Treatment of a stallion with low sexual drive is directed best at correction of the underlying problem. However, assessment of the nature of the problem frequently is difficult. One may try several alternatives, such as the following:

1. Change of stimulus mare or environment.
2. Breeding or collecting another stallion in the presence of the low libido animal.
3. Intravenous administration of Gn-RH, 50 μg, 2 hours and 1 hour before breeding or of LH (human chorionic gonadotropin), 5000 to 10,000 IU, 1 hour before breeding.
4. Single injection of a short-acting testosterone.
5. Intravenous administration of diazepam at a dose of 0.05 mg/kg (maximum 20 mg) 10 to 15 minutes before breeding to reverse mild shyness in some stallions.[45]

The efficacy of most of these treatments is empirical and awaits further investigation; however, chronic administration of steroids, particularly androgens, is well documented to affect spermatogenesis negatively.[46] Therefore injection of stallions with exogenous steroids and particularly androgens to improve libido is not a recommended practice.

16.10.2.1.5 Erection Failure

The inability of a stallion to develop and maintain a normal erection despite normal libido suggests an anatomic rather than a psychogenic problem. The most common problems are vascular damages associated with traumatic injuries or neurologic problems associated with other penile or lumbosacral compromise.[47] Therapy of either problem, extrapolated from the human literature, may be medical with injection of vasoactive drugs directly into the corpus cavernosum or surgical with penile implants. To date, no reports indicate either procedure has been used in horses. No reports of dose or efficacy exist to support the use of Viagra in these stallions; anecdotal reports of its use suggest that results are inconsistent.

16.10.2.1.6 Ejaculatory Dysfunction

Some stallions show normal precopulatory behavior, mount, and copulate but fail to ejaculate. These stallions often attempt to ejaculate and may become exhausted or frustrated, becoming aggressive with the mare or handler. Before attempting to treat an ejaculatory dysfunction, one must examine the horse for evidence of degenerative joint disease in the hocks, spine, vertebrae, and pelvis and for lesions or

malformations in the hoof or foot abscesses. Recently, circulatory problems leading to iliac thrombosis have been reported to be associated with ejaculatory dysfunction.[48] Although difficult to diagnose, one always should consider psychologic problems that can lead to ejaculatory dysfunction when no organic causes can account for the problem.[47] Often typical behavior provides hints to the clinician about the psychogenic nature of the dysfunction. In most instances, psychogenic ejaculatory dysfunction results from traumatic accidents associated with breeding. If the role of musculoskeletal pain in ejaculatory dysfunction is uncertain, one may treat the horse with 1 g of phenylbutazone every 12 hours for
approximately 2 weeks. If the stallion refuses to ejaculate only under specific circumstances such as into 1144
an artificial vagina or when breeding a mare, the systematic approach of a patient, knowledgeable, and 1145
creative person is important to determine the problem. A variety of behavioral and managerial aids have been used to assist the stallions toward ejaculation.[49] One should adapt these aids according to the physical condition of the stallion, that is, a stallion that cannot achieve a full erection, stallions with difficulty mounting, or stallions that refuse to ejaculate after normal erection, mounting, thrusting, and belling of the glans. Neither mounting nor full erection are necessary for ejaculation. Stallions with difficulty mounting can be taught to ejaculate on the ground by stimulating the penis manually or with an artificial vagina. Stallions with erection problems ejaculate, provided that proper stimulation is given to the penis. One can achieve proper stimulation to the penis by raising the temperature of the artificial vagina or by applying hot towels to the base of the penis during thrusting. One also should consider changes in footing and surroundings, stimulus mare, handler, etc. before implementing pharmacologic therapy.[50]

Therapeutic regimes for ejaculatory dysfunction are empirical and include those already mentioned for the treatment of low libido stallions. In addition prosta-glandins, oxytocin, and xylazine have been used to aid stallions in the process of ejaculation. Oxytocin and prostaglandin also have been used to treat azoospermia caused by ampullary blockage.[51] The tricyclic antidepressant imipramine has been used orally to lower the threshold for ejaculation in stallions.[52] The doses for these products are discussed next.

16.10.2.1.7 Other Behavioral Problems

In addition to the previously described problems, stallions may have other abnormal behavior and vices that could eventually limit their fertility. These problems include overaggressiveness or stereotypies such as weaving, cribbing, wall kicking, and stomping.

Overaggressiveness is managed best by a good stallion handler and patience; in most cases the problems can be corrected. Stable vices often can be solved or somewhat alleviated by introducing a toy (rubber tire) or a companion animal (goat or sheep) into the stall with the stallion.

One of the most complex behavioral syndromes observed in stallions is self-mutilation. Although purely speculative, this problem has been proposed to have a genetic component. The stallion compulsively nips or bites the chest, shoulder, or flank or aggressively kicks the walls. Although self-mutilation is limited to postpubertal horses, it is not limited to confined animals. In some animals the problem is exacerbated on presentation of a mare to a confined stallion or breeding in the presence of another stallion.[53] The compulsive behavior seems to be more dramatic during the breeding season. Self-mutilation may be a problem exacerbated by olfactory stimuli. In most horses this behavior is triggered by smelling their own manure. The stallions in many instances recognize themselves as a threat, triggering the compulsive behavior. One must ensure that the horse does not develop the behavior out of frustration because of chronic pain such as an inguinal testicle or chronic gastrointestinal ulcers.

Therapy of this complex syndrome includes regular exercise, stall toys, or companion animals. One can use products to reduce the olfactory sense along with a reduction in the level of energy in the diet. Treatment with L-tryptophan in the grain also may be helpful for some horses. Physical restraint such as head cradles or muzzles most likely will lead to development of an alternate self-mutilating technique.[53] In extreme, inhumane, and refractory cases, castration of the stallion has eliminated the problem.

16.10.2.2 SEMEN COLLECTION

In addition to appropriate libido and behavior, a stallion must have good mating ability and be able to deliver an ejaculate. Mating ability and semen quality may be influenced by hereditary or environmental factors or learned patterns that are influenced greatly by management. An integral part of the diagnostic workup on a stallion with known or suspected infertility is the collection of semen. The collection process is critical because improper technique may result in poor fertility or inferior semen quality.

16.10.2.2.1 Semen Collection Area

The area used for semen collection should be spacious, dust free, clean, and free of distracting noises, animals, and person. The size of the breeding shed should be designed with awareness for the space needed for animal and human safety in the event of an uncooperative mount mare or unruly stallion. Stallions with low libido or reluctance to mount frequently are encouraged to mount a mare in estrus if the mare can be walked slowly forward or led in a large circle. There should be adequate space to permit safe handling of the stallion and mare. Additionally, the footing surface should afford the stallion good traction even when the flooring is wet.[54] Many stallions paw, strike, or kick out while teasing a mare, being washed, or after dismounting. One should remove loose dirt, stone dust, and shavings because some stallions paw debris and dust onto the washed, damp penis just before mounting. If the collection area is dusty, the area should be wetted regularly.

Collection of semen in an outside area is acceptablein most cases but on occasion may compromise semen collection because of distractions by other animals, persons, and vehicles. Ambient temperature also may 1145
have a great effect because it alters the rate at which the temperature of the artificial vagina declines during 1146
cold weather or adversely effects semen quality during hot weather. Semen collection in an outside, grassy area affords the stallion, mare, and handlers the best footing; is usually free of dust; and allows for plenty of space for safety. The distance from the semen collection area to the laboratory should be minimal.

16.10.2.2.2 Semen Collection Techniques

One can collect semen from stallions by using natural breeding with a condom; pharmacologic stimulation of ejaculation; manual manipulation of the penis; or an artificial vagina on the ground or on a mount. Under certain circumstances, one may find it necessary to use any one of these methods. However, for routine collection of semen for commercial use, an artificial vagina (AV) or manual stimulation of the penis of the stallion are the methods of choice.[52,55]

16.10.2.2.2.1

Condom

One fits the stallion with a latex condom and allows him to breed the mare naturally. Immediately after ejaculation and when the stallion has withdrawn the penis from the vagina, one retrieves the condom. Semen collected using the condom method is contaminated heavily by bacteria and debris. This method also requires that a mount mare be in estrus and increases the riskof mare contamination of the penis by vaginal entry, urination, and defecation during natural breeding. Many stallions do not tolerate breeding while wearing a condom. Condom and semen loss are also common. However, a stallion accustomed to natural service occasionallymay be intolerant of semen collection with an AV until adequately trained for this method of breeding.

16.10.2.2.2.2

Pharmacologically Induced Ejaculation

Numerous schemes have been published for the ex copula ejaculation of stallions using xylazine, imipramine, xylazine and imipramine, and prostaglandin.[42,56–58] Semen collected in this fashion is of low volume and high concentration. One can use the resulting ejaculate for cryopreservation or artificial insemination of mares in a cooled semen shipment program. Fertility with the fresh, cooled semen is normal. However, the inability to obtain ejaculates on a predictable schedule limits the commercial usefulness of these methods. In experimental ponies, semen was collected in 10 of 24 attempts using imipramine and xylazine.[56] Under selected cases of physical inability of the stallion to mount and copulate, one possibly may obtain semen specimens with the aid of pharmacologic agents. Under farm conditions, one obtains semen in 25% to 30% of the attempts. Keeping the stallion quiet and undisturbed is important. One should give intravenous treatment quietly. One such successful schemeis to administer 2.0 mg/kg imipramine hydrochloride intravenously. If the drug does not induce erection and ejaculation within 10 to 15 minutes, one administers xylazine intravenously at the rate of 0.2 to 0.3 mg/kg. With imipramine and xylazine, ejaculation occurs in association with erection and masturbation. If one uses xylazine alone to induce ejaculation, masturbation and erection do not occur in association with ejaculation. Ejaculation usually occurs as the stallion enters a period of sedation or when he is recovering from the sedation. This method of semen collection was used in a cooled, shipped semen program for a stallion with severe tenosynovitis of a rear leg.[57] Although successful about 25% of the time, the procedure was time consuming and unpredictable for mare owners. Success rate may increase if the dosages are altered for individual stallions.

16.10.2.2.2.3

Manual Manipulation of the Penis

Ejaculates collectedby manual manipulation of the penis are similar to ejaculates collected in an AV. This method of collection has not received widespread acceptance because of the training and dexterity required by the person collecting semen from the horse. Many stallions fail to ejaculate unless trained for this method of collection.[49,55] A major advantage of this method of collection is that only one or two individuals are necessary for semen collection. The stallion is usually not in direct contact with a teaser mare. Specialized equipment or facilities are not necessary for semen collection by the manual stimulation method.

With manual stimulation of the glans penis for semen collection, the stallion remains standing on the ground or is trained to mount a phantom. The stallion may be trained for collection in his stall, an open

barn aisle, or a corner of the breeding shed. An estrous mare is usually nearby, but mare stimulation for the stallion may need to be altered based on stallion response. The horse is teased until erection occurs. The operator washes the penis of the stallion with warm water. Once full erection is achieved, the operator places a plastic sleeve or bag over the penis. The operator uses one hand to cup and stimulate the glans penis to achieve favorable thrusting and glans engorgement by the stallion. The operator uses the other to stimulate the base of the penis and urethra. The operator sometimes places a warm towel at the baseof the penis to increase stimulation. Training a stallion for this method of collection may require considerable patience, whereas other stallions readily accept the procedure. Stallions trained for this method of semen collection become habituated to the routine of sights, sounds, and activities surrounding semen collection. These stallions may require little stimulation by a mare.

16.10.2.2.2.4 Ground Collection

Ground collection may be particularly beneficial in stallions with tarsal arthritis, rear fetlock or tendon injury, laminitis, or hindlimb weakness associated with neurologic disease. The need for an estrous mare 1146
usually is eliminated, risk of injury to the horse by the mare is prevented, and one less handler is needed. 1147
This method of semen collection has been most useful on small farms that stand a stallion for artificial insemination and do not have adequate personnel and facilities for mare and stallion handling and collection.[54]

Collection can be done in the breeding shed or barn aisle or in the stall. One exposes the stallion to another horse that can stimulate the stallion to achieve an erection. The teaser animal may be free in a stall or 5 to 10 m away, being held on a lead shank. One washes the penis of the stallion with clear, warm water. With the stallion positioned against a smooth wall to prevent lateral movement or in front of a solid wall to prevent his forward movement, one places the warm, lubricated AV on the erect penis and encourages the stallion to search and thrust into the AV. Once the stallion has engaged the AV, the collector uses the right hand to stimulate additional urethral pulsations while holding the AV against the abdomen of the stallion with the left hand. The stallion handler may help support the stallion by pushing against the shoulder of the stallion with the right hand. For safety reasons, the person collecting the semen always should maintain shoulder contact with the stallion.

Stallions may stand on their rear legs or walk forward slowly while ejaculating or continue to stand with all four feet on the ground. The handler should not discourage the horse from walking forward or standing up. Once horses are trained to the procedure, they usually stand flat-footed with arched back and a head-down posture. At first application of the AV to the standing stallion, a few stallions may kick out or want to nip or bite at the handler. The veterinarian should inform the handler of the stallion and mare of likely responses before initiating this method of semen collection. After a successful collection, one repeats the procedure in 1 to 2 days, preferably in the same location with the same handler and collection person. A lightweight model of AV is recommended for this procedure.

The author has had good success by placing the chest of the stallion against a phantom when a stallion is not trained to mount. The thrusting into the AV in most cases results in the stallion elevating his front quarters, resulting in the collection on the mount.

16.10.2.2.2.5 Artificial Vagina

Semen collection using an AV is the most widely used method of semen collection from stallions. Many models of equine AVs are available. The AV is fitted with a water jacket that allows for the passive

control of the internal temperature of the liner, usually at 44° to 48° C. In most cases, one can modify the internal diameter of the AV by the addition of water or air to the water jacket. One adds a lubricant manually to the innermost liner of the AV to alter the degree of friction during breeding. One should avoid lubricants containing bacteriostatic or spermicidal compounds because they are likely to be detrimental to sperm motility and fertility.[59] One may use Vaseline or petroleum jelly safely. One can modify most commercially available AVs to allow incorporation of a filter into the semen collection system, if desired, so that one can remove dirt, debris, and gel from the semen sample. Otherwise, one can filter the entire ejaculate after collection or can aspirate the gel from the sample using a syringe. Most sperm losses during collection are accounted for by the filter and in the gel fraction of semen. Twenty-five percent to 30% of sperm in an ejaculate can be lost in the gel and filter. Types of filters one can use are paper, polyester, or nylon, with paper retaining the most sperm.[60]

Ideally, the AV should be constructed to maintain the desired temperature for a significant period of time, allow the direct ejaculation into the semen receptacle, and allow for ease of handling and manipulation by the operator. If the AV is large and heavy, the operator may have difficulty positioning the AV for tall stallions or holding it in place in cases where the mount mare moves during collection. For the collector to be able to hold the AV in one hand at the appropriate position while using the other hand to deflect the base of the penis to the side of the phantom or mount mare is best. The arrangement is particularly helpful in stallions that thrust with significant force. Deflecting or stabilizing the base of the penis is stimulatory to most stallions and may help prevent penile accidents during collection.

Semen collection failures frequently are associated with inappropriate AV positioning for the particular stallion; an AV that has dropped in temperature below a critical point for the stallion; and the use of excess pressure in the AV. One should hold the AV parallel to the ventral abdomen of the stallion and directly aligned with the base of the penis. In this manner one avoids ventral or lateral bending of the penile shaft. In addition, one must ensure that the forceful thrusting of the stallion does not result in the forward movement of the AV, for this will result in the stallion searching for the end of the AV and in most cases failing to ejaculate. In certain circumstances, stallions having difficulty ejaculating into theAV necessitate elevating the internal temperature of theAV to 50° C. However, one should make an effort to have the horse ejaculate directly into the semen receptacle or coned portion of the AV liner to avoid heat shock to the sperm. Sperm cells exposed to excess heat from the AV liner exhibit a circling type of motility, have reduced sperm longevity in raw and extended semen, and may be rendered infertile. Exposure of semen to elevated temperatures for as little as 10 to 20 seconds is sufficient to cause heat shock damage.

16.10.2.2.2.6

Selection of an Artificial Vagina

All AVs used for semen collection from stallions are basically similar in that they have a water jacket 1147
that allows variation in the internal temperature and pressure of the AV liner. The specific 1148
characteristics of individual AV types vary in the overall length of the AV, its diameter, ease of filling the water jacket, ease of handling, weight of the AV, and location of ejaculation within the AV by the stallion. Commonly used AV models include the Missouri, Colorado, Hanover, Nishikawa, HarVet, and Polish models.[43,54]

16.10.2.2.2.7

Missouri.

The Missouri AV is used commonly in the United States. The Missouri AV is the least costly and is easy to clean. This AV does not need to be assembled for each use because the water jacket is formed by two molded layers of latex rubber. A single rubber cone leads from the water jacket for attachment of a semen receptacle. The AV is held by a leather case with leather handle. Addition of water or air to the water jacket allows for adjustment in AV temperature and pressure. In most instances, the glans penis of the stallion is beyond the warm water jacket at the time of ejaculation so as to avoid heat shock damage to sperm. One can attach a clean plastic or glass bottle, a Whirl-pack bag, or a disposable baby bottle liner to the AV for use as a semen receptacle. One also can incorporate a filter into the semen receptacle.

16.10.2.2.2.8

Colorado.

The Colorado model of AV is substantially longer, larger in diameter, and heavier than other AVs when ready for use. The AV consists of a solid outer plastic casing and is assembled by adding two layers of rubber liners to the casing to form the water jacket. This AV maintains the working temperature for stallions for a significantly longer period of time. Because of the weight and size of this AV, some operators have difficulty holding the AV in the most appropriate position for some stallions. A significant shortcoming of the Colorado model AV is that most stallions ejaculate midway along the length of the warm-water liner, exposing sperm cells to high temperatures. The operator needs to be extremely cautious when using this AV to avoid heat shock to sperm. Disposable filters and liners are available for the Colorado model AV to remove gel and reduce bacterial contamination from the rubber liners.

16.10.2.2.2.9

Hanover.

The Hanover model AV is used commonlyin Europe, is shorter and smaller in diameter than the Colorado AV, and is made of a hard rubber casing and inner rubber liner. This AV should work well for most stallions. Ejaculation occurs at or near the end of the water jacket.

16.10.2.2.2.10

Nishikawa or Japanese.

Although the Nishikawa or Japanese AVs are no longer available in the United States, replacement latex liners are still available. The aluminum casing makes this a lightweight, easy to handle model, and most stallions ejaculate directly into the semen receptacle.

16.10.2.2.2.11

HarVet.

The HarVet AV closely resembles the Nishikawa AV in its light weight and similar size with a plastic casing. This AV is designed to be used with disposable AV liners that form a semen receptacle atits distal end and therefore avoiding the water leakage problem of the Nishikawa AV.

16.10.2.2.2.12

Polish or Open-Ended Artificial Vagina.

The Polish model is substantially different from other models on the market. Using the open-ended AV, one can visualize the process of ejaculation and can collect individual jets of presperm, sperm-rich, or gel fraction of semen. This AV has been valuable in the diagnosis of hemospermia, urospermia, internal genital tract infections, and ejaculatory failure.[61] Additionally, this AV has been useful in obtaining semen for commercial use from stallions with hemospermia and urospermia, because most of these affected stallions ejaculate the blood or urine after the initial jets of sperm-rich semen. The open-ended AV also has been useful in cryopreservation programs to obtain sperm-rich and bacteria-free ejaculates from stallions. One also can use this method of collection to obtain "clean" ejaculates from stallions that are untrained and intolerant of penile washing. The Polish AV also allows the use of high internal AV temperatures without the risk of sperm cell damage because the ejaculate usually is emitted directly into a funnel with an attached receptacle held by a second person.

Open-ended AVs are not currently available in the United States but can be homemade from plastic or polyvinyl chloride tubing or by removing the coned portion of the Missouri model AV and using only the innermost rubber liner to form a water jacket.

To reduce the risk of chemical residue exposure ofthe semen from the AV liner cleaning process or to allow the use of the same AV by multiple stallions, sterile, plastic disposable liners have become commercially available for most types of AVs. However, many stallions object to these liners, and the number of mounts per ejaculation increases. Breakage of the plastic liner may occur during thrusting, and complete eversion of the liner may occur during dismount. If stallions ejaculate on first entry into an AV fitted with a disposable liner, the bacterial contamination of semen is reduced sharply. However, as the number of entries into the AV or the number of thrusts in the AV increases, the bacterial contamination of semen also increases.

One should clean the AV immediately after each use, should rinse it thoroughly with hot water, and should wipe away dirt, debris, and smegma. If one does not use disposable liners, one should immerse the rubber liners in 70% alcohol for 1 hour or more, rinse the liner thoroughly with hot water, and hang the liner in a dust-free, dry environment. One should not use soaps and disinfectants on the rubber equipment to avoid accumulation of chemical residue by the rubber. Without the use of disposable AV liners or thorough cleansing of theAV and its liners, the AV may become contaminatedby *Pseudomonas* 1148
spp., *Klebsiella* spp., *Escherichia coli*, *Taylorella equigenitalia*, or other harmful bacteria and therefore 1149
contaminate subsequent semen samples and inoculate the penile surface of the stallion. For these reasons, many farms maintain an individual AV for each stallion at the breeding farm.

16.10.2.2.3

Selection of a Breeding Mount

One can collect semen from the stallion while the stallion is mounted on a behaviorally estrous mare, phantom mare, or breeding mount or while the stallion is standing on the ground.

16.10.2.2.3.1

Live Mare

Selection of a suitable mount mare frequently depends on the experience and breeding mannerismsof the stallion. For example, the novice, inexperienced stallion may need to be taught to mount the mare

from the rear quarters. This training requires a disciplined, cooperative mount that will tolerate being mounted from the side. Some stallions vocalize loudly in the breeding shed and may frighten maiden or timid mares. The mount mare needs to tolerate a certain amount of nipping and biting of the neck, shoulders, flank region, and hocks to be suitable for some stallions. Mares with foals at their sides are frequently protective of their foals and less cooperative than barren mares. The mount mare also should be an appropriate size match for the stallion. For routine breeding farm activities, the reliance on an estrous mare as a mount has significant shortcomings. Additionally, in a cooled, shipped semen program, the breeding farm may not have access to nonpregnant mares, particularly at the end of the breeding season. Therefore some breeding farms maintain one or more ovariectomized mares as mount mares. One should select from these ovariectomized, mount mare candidates based on their size, tolerant attitude toward handling, and their strong estrous behavioral signs as intact mares. A mare with gonadal dysgenesis (XO) may be a good mount mare candidate without having to perform an ovariectomy. Most ovariectomized mares perform well as mount mares while being restrained with a twitch or lip chain placed on the upper gum. In some cases, one may need to administer a low dose of estradiol cypionate (0.5 to2 mg) at intervals of 3 days to 3 weeks to maintain receptivity by the mare.

During the semen collection process, one usually restrains the mount mare using a twitch. One also may apply hobbles to rear pasterns or hocks, but the novice, untrained stallion may become entangled in the hobbles if the collection procedure does not go as planned. One should wrap the long tail hairs at the base of the mount mare to prevent the tail from interfering with deflection and entry of the penis into the AV.

16.10.2.2.3.2

Phantom Mare or Dummy

Because of the lack of readily available mount animals, increased expertise required of an additional horse handler, and increased safety risks encountered while using a mount mare, many farms prefer to train the breeding stallions to mount a phantom or dummy mare for semen collection. Most stallions, including novice stallions, readily accept the phantomas a mount during semen collection. The working area around the phantom should be dust free and allow good footing by the stallion. Adequate space should surround the phantom for the safety of the handlers and to allow a teaser mare to be positioned alongside or in front of the phantom. Many stallions are trained to mount the phantom even when the teaser mare is not close to the phantom.

When one collects semen from a stallion using the phantom, the stallion should approach the mount in a controlled fashion, mount the rear of the phantom, and use his forelimbs to stabilize himself by grasping the padded barrel of the mount. The operator should quickly deflect the penis to the side of the phantom. While on the left side of the stallion, the operator deflects and stabilizes the base of the penis with the right hand. This practice minimizes potential injury to the penis and prepuce during thrusting by the stallion. Some phantom mounts are fitted with a Colorado type AV on the posterior end, which works well for some stallions and requires only one person for the collection procedure. However, some stallions need manual stimulation that is easierto provide when the operator has control of the AV. Stallions regularly used for live cover breedings can be difficult to train to accept the phantom as a suitable mount. For this reason, certain circumstances may require access to an estrous mare.

The breeding phantom usually is made of a hollow cylinder with closed ends. The barrel is covered with 1to 2 inches of firm padding. The padded cylinder thenis covered by a tough, nonabrasive cover that is free of wrinkles. Stallions that repeatedly mount and dismounta phantom abrade the medial aspects of the forearmsand knees. The stallion should be taught to dismount the phantom in a controlled manner by

backing offof the mount rather than making a side dismount. The diameter of the body of the phantom should be 20 to24 inches total. One should keep the legs of the phantom away from the mounting end of the phantom to avoid injury to the hindlegs of the stallion during breeding and dismounting. The mount should be adjustable for height, and the angle of the phantom should be adjustable to accommodate older stallions, stallions with hock problems, and stallions of varying stature.[54,62]

16.10.2.2.3.3 Semen Collection Procedure

Preparation and planning are the keys to the efficient collection of semen from stallions and to assure proper handling of the semen immediately after collection. The laboratory should be prepared so that the 1149
equipment and any extenders used in semen handling after collection are clean and at the desired 1150
temperature (35° to 37° C). One then assembles the AV and fills it with warm water (usually at 48° to52° C) because the AV equipment quickly drops the temperature during equilibration. One adjusts the final temperature of the AV, if necessary, to 45° to 48° C for most stallions; lightly lubricates the inner liner using a nonspermicidal lubricating gel; and adjusts the AV pressure at this time.

One selects a suitable area for semen collection. If an estrous mare is to be used as a mount mare, one should wrap the tail of the mare and wash her perineal areato prevent undue contamination of the stallion's penis during mounting. With the mare adequately restrained, one brings the stallion in to the collection area. Oncethe stallion has achieved full erection, the operator cleans the penis with clear, warm water, wipes the urethral diverticulae clean to reduce bacterial contamination of the semen further, and wipes the penis dry, if necessary, using a clean, soft towel.

The operator presents the stallion to the side of the mare and encourages him to mount after achieving a full erection and after the mare has demonstrated her receptivity. For safety reasons, the mare and stallion handlers should be on the same side of the mount mare as the individual collecting semen from the stallion. After the stallion has mounted, the operator directs the erect penis into the AV using the hand placed on the ventral surface of the penis. This hand continues to stabilize and deflect the base of the penis during thrusting and ejaculation. The operator should hold the AV to accommodate the stallion, which usually involves holding the AV parallel to the ventral abdominal wall of the stallion. Just before ejaculation, the operator can feel strong urethral pulsations with the right hand. Once ejaculation begins, the operator should tilt the AV downward to allow rapid entry of semen into the collection vessel to avoid heat shock to the sperm.

One conducts semen collection from the stallion mounted on a phantom in this same manner. As soon as the stallion dismounts, one takes the semen to the laboratory for processing and evaluation.

16.10.2.3 SEMEN EVALUATION

Depending on the reason for semen collection andits ultimate purpose, the ejaculate must be handled, processed, and preserved in different ways. Evaluation of raw semen for a routine breeding soundness examination or a prepuchase examination might need more detailed analysis than that done for semen collected regularly for an artificial insemination program at the farm. However, semen that will be processed for an artificial insemination program away from the site of collection requires different processing.

16.10.2.3.1 Evaluation of Raw Semen

The goal of most semen evaluations is to try to predict the fertilizing ability of a given ejaculate or the potential fertility of the animal undergoing the evaluation. However, the low predictive value and frequent lackof objectivity of traditional tests such as motility and morphology has led to the refinement of old techniques and the development of new methodologies for semen evaluation.[63] The standard evaluation of a given ejaculate involves the following:

1. Volume and color. One should record the color and volume (in milliliters) of the ejaculate. In general, color of the ejaculate ranges from watery to creamy and depends on the sperm concentration per milliliter. Abnormal colors or volumes can indicate contamination of the ejaculate with blood, urine, or pus. Normal volumes of ejaculates range from 20 to 250 ml, with an average of 50 to 60 ml.[64] Factors that influence the volume are degree of sexual stimulation before collection, breeding conditions, and foreign material in the ejaculate. Low volumes of ejaculate with low sperm concentration in an otherwise normal stallion suggest an incomplete ejaculation, and one should collect another sample.

2. Osmolarity and pH. Osmolarity of stallion semen ranges from 290 to 310 mOsm. Values greater than 350 mOsm can indicate urospermia, and one should measure the level of creatinine. Values less than250 mOsm suggest water contamination. Seminal pH ranges from 6.9 to 7.5, and values higher than those should warn the clinician regarding the possibility of extraneous material in the ejaculate or an infectious process in the reproductive tract of the stallion.

3. Spermatozoal motility. Sperm motility is a rough estimate of the percentage of viable sperm in the ejaculate. Several methods have been used to evaluate motility. First, *visual motility* is the most widely used assay for evaluating semen because of its simplicity and low cost. However, many factors greatly influence the evaluation: individual judgement, thickness of the sample, concentration of sperm in the ejaculate, degree of contamination, degree of agglutination, and temperature. For this reason, one should estimate motility by evaluating a number of fields in a 10 μl drop of well-mixed semen in a microscope with a heated stage.[43] Conversely, one can estimate motility by diluting a portion of the ejaculate with extender to a concentration of 25 to 50 × 10^6 sperm per milliliter.[65] Even under the most tightly controlled conditions, repeatability of visual motility is poor between technicians and laboratories. Visual motility estimates of freshly ejaculated stallion sperm have been reported to account for only 50% to 70% of the variation of fertility in that 1150
sample. The correlation is even worse (r = 0.3) when trying to predict fertility of a frozen-thawed 1151
sample of semen based on postthaw motility.[66] Second, *computer-assisted semen analysis* provides data on characteristics of sperm such as linear velocity, linearity, path velocity, and lateral head displacement that otherwise would be difficult to obtain. In addition, computerized analysis provides information on sperm concentration and percentage of motile cells. Although analysis of sperm motion with a computer is more objective and provides a highly consistent way of evaluating spermatozoa, the fertility of stallion sperm is not well correlated with any of the sperm characteristics measured with these analyzers.[67]

4. Longevity of sperm motility. One can determine duration of motility on raw, undiluted semen or on extended semen. Dilution factor of semen to extender affects the longevity of sperm, so ratios of 1:3

to 1:4 are recommended. To evaluate longevity of motility, one should evaluate semen samples immediately after extension and at regular intervals thereafter for up to 96 hours.[65]

5. Sperm morphology. Several attempts have been made to try to correlate the percentage of morphologically normal sperm present in a given ejaculate with fertility.[68,69] However, because of the lack of consistency among clinicians in reporting sperm morphology, results have been inconclusive. Among the problems that clinicians encounter are the definition of normal and abnormal in light of the tremendous range of normality and the fact that little knowledge exists regarding specific sperm defects that interfere with fertility. This problem is even more notorious when a clinician is trying to interpret the results from a referring veterinarian or a veterinary technician. One can avoid some of these inconsistencies by recording specific morphologic defects rather than grouping defects into primary and secondary because this last method erroneously assumes origin of sperm defects (i.e., testis and posttesticular, respectively). For any sperm morphology evaluation, one should count a minimum of 200 cells. One should record normal sperm cells as well as those with acrosomal, head, midpiece, droplets, and tail defects, noting the specific type of defect for each part. Although only 200 cells are counted routinely, one should record sperm cells with more than one defect as such to help the clinician evaluate the incidence of defects in a particular semen sample. One can evaluate cells as wet mounts under phase-contrast microscopy or differential interference contrast microscopy after fixation in buffered formal saline or 4% glutaraldehyde. If samples are to be preserved for longer periods of time, one should add an antibiotic to the fixative. Alternatively, one can evaluate cells after staining. One should mix one drop of semen well with the stain and then smear it on a glass slide. Common stains currently used include India ink, eosin-nigrosin, eosin–aniline blue, Giemsa, Wright's, and several others. The clinician should be aware that severe changes in osmolarity of the stain as well as mechanical damage to the sperm could alter the normal morphology of the cells.

One can gain additional morphologic information by performing scanning or transmission electron microscopy. Although these procedures are not recommended as a routine, they can prove valuable in cases of stallions with unexplained infertility.

16.10.2.3.2

Alternative Assays for Sperm Evaluation

Other assays for evaluating sperm in stallion semen include the following:

1. Hypoosmotic stress test. As with many other cells, when sperm with intact membranes are exposed to hypotonic solutions, the influx of water across the intact membrane causes swelling of the cell and is evident by a characteristic coiling of the tail.[70]

2. Flow cytometry. Flow cytometry now is used widely to evaluate stallion spermatozoa. This technique, based on labeling of sperm acrosomes or DNA with fluorescent dyes, has the advantage of analyzing a large population of cells, which in turn provides information on the distribution of acrosomal or chromatin integrity.[71–73]

3. Biochemical evaluation. Activity of enzymes such as aspartate aminotransferase, glutamine-oxaloacetic transaminase, lactate dehydrogenase, adenosine triphosphate, hyaluronidase, and acid and alkaline phosphatase are correlated positively with the numberof sperm in the ejaculate. Because these enzymesare located mostly in the acrosome or midpiece, their activities—particularly those of glutamine-oxaloacetic transaminase, lactate dehydrogenase, and hyaluronidase—increase

proportionally with the level of damage inflicted on the sperm. Therefore one can use enzyme activities in the seminal plasma as indicators of the degree of acrosomal or membrane damage.[74–76] Further research is needed in this area to establish normal enzyme activities in stallion seminal plasma.

16.10.2.3.3 Preservation of Semen

The specific processing of the ejaculate is determinedby how long the semen needs to be stored before insemination. Semen can be used fresh, cooled, or frozen.

16.10.2.3.3.1 Fresh Semen

Semen that is collected and used immediately or up to 12 hours later need not be refrigerated and in most cases can be diluted with appropriate prewarmed extender at ratios of 1:1 to 1:4, depending on raw semen concentration and ejaculate volume. Immediately after extension, one should remove semen from 1151
the incubator and cool it to room temperature (15° to 20° C) without loss of its fertilizing potential. One 1152
may use raw semen for artificial insemination within 30 minutes to 1 hour after collection, provided that it is kept at 37° C. Extension of all collected semen before insemination is highly recommended.[77]

16.10.2.3.3.2 Chilled Semen

To retain its fertilization potential, semen that is going to be used 12 and up to 72 hours after collection should be cooled to 5° to 8° C. Besides storage temperature, the most important factors affecting the longevity of extended semen are semen quality, sperm concentration immediately after ejaculation, type of extender and antibiotic used, and dilution rate and cooling rate. Several systems of passive cooling for stallion semen are available; however, the Hamilton-Thorn Equitainer System has proved to provide excellent cooling rates and is considered the most reliable method for shipping cooled semen. In addition to cooling the semen at an appropriate rate, the Equitainer maintains the semen at the desired temperature for up to 72 hours. Furthermore, the Equitainer II has been shown to be the most appropriate container to use if the container is likely to be subjected to freezing conditions for an extended time.[77]

One should dilute semen at a ratio of 1:3 to 1:10 depending on the initial volume and concentration of the ejaculate. In general, longevity of fresh cooled sperm is directly proportional to the dilution ratio, ensuring that the total dose has 1 billion sperm cells and concentrations between 25 million and 50 million sperm per milliliter.[77]

Idiosyncratic differences in individual stallion semens in tolerance of the cooling process or particular extenders are not uncommon. Although the factors that determine why some semen samples from some stallions do not preserve well are unknown, particular components in the seminal plasma, such as oxygen free radicals, are suspected of being involved. In fact in some instances, one can improve longevity and fertility of some stallion semen substantially by removing the seminal plasma and resuspending the semen in the appropriate extender.[78]

When processing or evaluating shipped semen, one must remember the following:

1. Extenders should have an antibiotic. The combination of amikacin and potassium penicillin is popular and does not appear to interfere with fertility.
2. The modification of the traditional nonfat, dried milk solids–glucose extender may improve semen quality of selected stallions, especially if all seminal plasma is removed.
3. Semen-to-extender dilution ratio may need to be altered for each individual ejaculate with dilutions of 1:5 or greater not being uncommon.
4. One should select a commercial storage container in light of the transport time, method of shipment, and ambient temperatures to which the container will be exposed.
5. The use of nontraditional laboratory probes, such as the Sperm Chromatin Structure Assay, can provide meaningful information regarding the effects of semen storage on spermatozoal function.

A common practice for some breeding farms is to ship semen for two inseminations 12 hours apart. In recent years it has become evident that mammalian sperm, including stallion sperm, reaches the oviduct within a few hours after insemination and subsequently attaches to the oviductal epithelium and remains motile for at least 72 to 96 hours. This has led researchers to suggest that the oviduct of the mare is a better storage place than any of the transport systems available. Therefore using all available semen for insemination of the mare as soon as it arrives is highly recommended. However, one must take into account sperm quality and reproductive history of the mare to decide if the uterus of the mare can tolerate two inseminations.

16.10.2.3.3.3

Freezing Semen

When the semen is intended to be inseminated more than 72 hours after collection, it must be frozen to retain some of its fertilizing potential. The only successful way to preserve sperm for long periods of time, that is, for months or years, is cryopreservation or freezing. Different stallion semens tolerate differently the freezing and thawing process, and unfortunately, the number of motile sperm after thawing is a notoriously poor indicator of fertility of frozen-thawed semen.[78]

In general, the freezing process involves the collection of semen from the stallion, evaluation of the semen, dilution and centrifugation of the semen, and resuspension of the sperm in freezing extender. Unfortunately, frozen-thawed sperm appears to have a shorter life span in the reproductive tract of the mare than raw semen or fresh sperm. The reduced life span appears to be related partially to differences in calcium metabolism between fresh and frozen sperm.[79] Because of the apparent short life span of frozen semen, timing of insemination appears to be critical when using frozen semen.

16.10.2.3.3.4

Semen Processing for Freezing.

Unfortunately, the equine frozen semen industry is still in its infancy. The lack of standardization of the procedure, the lack of laboratory test(s) that relate to fertility, and the idiosyncrasy of some stallion semens to tolerate the freezingand thawing process have been major obstacles in the development of standard freezing techniques.

Extenders for freezing stallion sperm need to have energy and protein sources similar to that needed by fresh or cooled semen. However, in addition, freezing extenders must contain a cryoprotectant such as glycerol.[80,81]

Semen that is intended for freezing should be processed as soon as possible. Although some stallion 1152
semens tolerate transportation well, processing the semen more than 1 hour after collection is not 1153
advisable.

The raw semen from stallions that is classified as a "good freezer" in general has a lower volume, higher motility, and higher number of total motile sperm than semen classified as a "poor freezers."[82] However, classification of stallion semen as a good or poor freezer based solely on the percent of motile cells after thawing is risky. One should perform longevity of motility, detailed morphology, and in some cases acrosomal and flow cytometric evaluations to determine the quality of the semen before its commercial use.[83]

Processing an ejaculate for cryopreservation involves the following steps:

1. Collection and evaluation of the raw semen.
2. Dilution of raw semen in a sugar- and protein-based extender.
3. Centrifugation of extended semen and removal of the supernatant.
4. Reconstitution of the pellet with freezing extender.
5. Packaging of the sperm in an appropriate packaging system after adjusting suspension to the desired number of sperm per dose.
6. Placement of straws in liquid nitrogen vapors or in a programmable freezer. One should identify each frozen unit with at least the name and breed of the stallion, registration number for that breed, date of the freeze, and identification of the laboratory processing the semen.

16.10.2.3.3.5 Thawing and Evaluation.

The handling of frozen semen greatly depends on the recommendations given by the laboratory processing the semen and the type of package in which the semen is presented. In general, single 0.5-ml straws are thawed at 75° C for 7 seconds or at 38° C for at least 30 seconds. When an insemination dose consists of multiple 0.5-ml straws, the most common thawing protocol is 37° C for at least 30 seconds, making sure that the straws do not stick together during the thawing period. Frozen semen packed in 2.5-, 4-, or 5-ml straws is recommended to be thawed at 50° C for 40 to 45 seconds. Regardless of the thawing protocol or packaging system, the well-accepted fact is that once semen has been thawed, it should be inseminated almost immediately.[43]

Although the freezing procedure is simple, the evaluation after thawing and the prediction of the potential fertility of a given ejaculate after thawing is not so simple. Sperm quality has a profound effect on the pregnancy rates achieved with frozen-thawed semen. Motility after thawing, concentration per dose, morphology, and acrosome integrity are parameters one should evaluate to determine the quality of frozen semen. Unfortunately, a battery of tests, let alone a single test, cannot predict fertility of

frozen-thawed sperm so as to determine what is good and what is poor semen. In general, semen with higher motility is considered to be of better quality; unfortunately, this is not always the case. The motility of most stallion semen after thawing, regardless of the motility before freezing, is 30% to 45% less than for fresh sperm. But some stallion semens with motilities of less than 30% after thawing have acceptable pregnancy rates per cycle, whereas others with motilities greater than40% have low pregnancy rates.[83,84]

16.10.3 Management of the Breeding Stallion

One should consider many things to optimize management of the breeding stallion, including feeding, exercise, and vaccination programs. One determines many management decisions by the number of mares that a stallion will breed in a season, breed, type of housing, and the method of breeding.

16.10.3.1 GENERAL MANAGEMENT

16.10.3.1.1 Feeding Program

Successful breeding programs require a balanced feeding program. Overfeeding and oversupplementing of stallions is probably the most common form of malnutrition in stallions. Obesity may affect libido and mating ability adversely. In general, the nutritional needs of a stallion during the breeding season do not appear to be different from those of maintenance. A maintenance ration consists of enough balanced nutrients to support normal, basic bodily functions. Adequate pasture or good-quality hay usually can meet these requirements. Free access to trace mineralized salt and fresh water ad lib are also necessary. Grain as an energy supplementin cold weather or under certain stressful conditionsalso may be warranted. The size, condition, activity, and temperament of the stallion play a role in his nutritional needs.

The healthy stallion consumes 2% to 3% of his body weight daily. At least 50% of this should be in the form of roughage.[85] Stallions generally require 10% proteinin their feed, with younger stallions requiring 12% to 14%.[86] Although micronutrients such as vitamins A and E, selenium, copper, and zinc play an important part in the successful completion of spermatogenesis, to date no evidence exists that any of these nutrients fed in excess increase sperm numbers or quality.

16.10.3.1.2 Exercise

Horses naturally are roaming and grazing animals. Exercise for stallions is an integral part of their management and affects their mental and reproductive well-being. The goal is to keep a stallion fit for the breeding shed, not the racetrack, so that he has a good attitude toward his daily duty, that is, covering 1153
mares. The amount of exercise time must be tailored to the temperament and needs of the stallion. Owner 1154
should provide regular exercise to maximize the fertility and longevity, as well as physical and mental fitness, of the stallion. In addition, lack of exercise may lead to vices such as weaving, stall walking, or cribbing.[87]

16.10.3.2 ESTIMATION OF STALLION BOOKAND FREQUENCY OF SERVICE

A stallion usually is chosen as a breeding animal basedon pedigree, performance, and conformation. Little or no emphasis is placed on reproductive potential, and a significant number of stallions enter the breeding pool

with poor or marginal fertility. A complete breeding soundness examination on maiden stallions or a complete review of past reproductive performance for new stallions is an integral part in the management process. Information concerning the number of mares bred, number of covers made, pregnancy rate per cycle, and covers per pregnancy is helpful in evaluating reproductive efficiency. If a stallion has stood at stud in previous breeding seasons, collection of one or two ejaculates is sufficient to determine that his semen quality has not declined during his off time because of illness, trauma, or age.

Libido of the stallion certainly can play a large role in determining the number of mares a stallion can service during a breeding season. Libido, which is thought to be a genetically acquired trait, can be modified by handling and environmental conditions such as housing. Therefore testosterone levels and libido can be altered by interaction between stallions and mares and with exercise. Many times, poor libido is a limiting factor in the number of mares a stallion can cover. The number of covers a stallion can make in a day varies with the individual stallion. Factors such as age, physical abnormalities, and testosterone levels play an important role. Some stallions can breed 2 to 3 times a day, 7 days a week, whereas some can cover only one mare per day.

The length of the breeding season also plays a rolein the number of mares the stallion can mate. The Thoroughbred season is generally from February 15 to July 15. Therefore the number of mares that can be presented during this time is limited in a natural breeding program. In Warmblood stallions, an excess of 350 mares can be bred with every other day collection of semen of average quality.

One must also consider the age and physical condition of the stallion. Stallions typically retire to stud at 3 to 5 years of age. Age influences reproductive capacity. Stallions reach puberty at 12 to 24 months of age but continue to mature and increase reproductive performance until at least 5 years of age or older. During the breeding season, seasonal fluctuation of sperm production occurs.[88] In addition, physical problems, especially of the hindlegs may limit the number of mares that the stallion can mount and service. Furthermore, the quality of the book of mares that the stallion has for a particular year can have a significant effect on the number of mares that he can cover. For example, a stallion that has a book in which most of his mares are maiden or young foaling mares will be able to cover significantly more than one who is booked to a majority of old barren mares.

The effect that the reproductive potential of a stallion has on the overall breeding program is significantly more important than that of a single mare. However, for veterinarians and managers to understand the complex interactions between management, endocrinology, and the quality of the mares that a stallion breeds is imperative so that they can diagnose or treat infertility problems in the stallion.[89] One can estimate potential sperm production by using the combined testicular volume as described in a previous section of this chapter.

16.10.3.3 STALLION AS A SOURCE OFDISEASE TRANSMISSION

With increasing breeding management—that is, more mares bred to a stallion on a given year—the significance of venereally transmitted diseases in horses has gained importance. Thoroughbred stallions commonly may breed more than 100 mares by natural cover and Standardbred or Warmblood stallions may breed twice that number, or more, in a single 5- to 6-month breeding season through artificial insemination. With the implementation of frozen semen technology, semen from virtually any country can spread disease in a country or continent far removed from the direct area of influence of the stallion.

Veterinarians must be aware of the risk factors for disease transmission, diagnostic methods, and some management measures that can reduce the incidence of disease with its potentially devastating effects on fertility.[90]

16.10.3.3.1

Risk Factors

Several risk factors may increase the chances of disease transmission through semen:

1. Natural mating: Direct sexual contact perhaps poses the biggest risk for venereally transmitted disease. One should culture all mares, but particularly those with poor fertility histories, before breeding. One should monitor stallions breeding by natural cover regularly.
2. "Backyard stallions": Stallions that are not standing at a breeding farm tend to have lower numbers of mares per season and poorer reproductive management. Hygienic procedures in these cases often are neglected, and these stallions or mares can be carriers of infectious disease. Often these horses are poorly housed, which can contribute to colonization of the penis by pathogenic bacteria.
3. Inconsistent breeding method: In breeds for which artificial insemination is allowed, a stallion 1154
   commonly may breed several mares by natural cover at the farm, under no veterinary supervision. 1155
   The owner also may request that semen from the stallion be collectedto be shipped to other mares. These inconsistent practices can increase the risk of a stallion becoming contaminated or of spreading microorganisms to several mares.
4. Artificial insemination: Artificial insemination has been advocated as a technique that greatly reduces the risk of disease transmission. Stallions breeding artificially could breed more than 200 mares during the year. These horses usually are scrutinized carefully for venereal diseases and are housed with other animals of similar health status. Other factors—such as the hygiene of the artificial vaginal, lubricants, collection bottles, dummy mount, or teaser mare and semen packing material—could serve as sources of contamination for venereal disease transmission. If cleanliness and hygiene factors are overlooked, the process of artificial insemination may serve as a multiplier of disease.[91]

16.10.3.3.2

Types of Disease

The types of diseases that can be transmitted through semen include bacterial, viral, protozoal, and genetic.[90]

16.10.3.3.2.1

Bacterial Diseases.

The source of bacterial infections can be from the external or the internal genitalia.

16.10.3.3.2.2

External Bacterial Infections.

Virtually every stallion and all ejaculates have contaminants that could be potential pathogens in the mare because a variety of commensal bacteria inhabit the surface of the penis and prepuce. These bacteria constitute the normal flora of the penis and rarely produce genital infections in reproductively

sound mares. One commonly can culture an unwashed stallion penis or fossa glandis and harvest a milieu of bacteria including *Escherichia coli, Streptococcus zooepidemicus, S. equisimilis, Staphylococcus aureus, Bacillus* spp., *Klebsiella pneumoniae*, and *Pseudomonas aeruginosa*.[92] However, when the normal bacterial flora is disrupted, potentially pathogenic bacteria, particularly *P. aeruginosa* and *K. pneumoniae*, can colonize the penis and prepuce. These organisms rarely produce clinical disease in stallions but can be transmitted to the genital tract of the mare at the time of breeding, resulting in infectious endometritis and associated subfertility. The factors that contribute to the colonization of the penis by these bacteria have not been determined clearly. Normal bacterial microflora of the external genitalia of the stallion may combat proliferation of pathogens, and frequent washing of the penis, especially with soaps, may remove these nonpathogenic resident bacteria, increasing the susceptibility of the penis and prepuce to colonization by pathogenic organisms.[93] Others dispute this concept, asserting that repeated washing of the external genitalia alone does not contribute to overgrowth of pathogenic microorganisms. The environment in which a stallion is housed may influence the type of organisms harbored on the external genitalia. The stallion also can acquire these organisms at the time of coitus with a mare that has a genital infection.[94]

One diagnoses pathogenic colonization of the stallion's penis first of all by careful evaluation of breeding records and early pregnancy diagnosis. A sudden and unexplained drop in pregnancy rates should warn the stallion manager about a possible problem. Definitive diagnosis is by isolation of the microorganism in culture. In addition, isolation of the same microorganism with a similar sensitivity pattern from the nonpregnant mares helps confirm the diagnosis.

Treatment of penile colonization depends on the type of bacteria and method of breeding. For stallions breeding by artificial insemination, a thorough penile wash before semen collection is recommended. One then dilutesthe filtered semen with extender containing antibiotic for which the bacteria is sensitive. Incubation should be for at least 30 minutes before insemination. Operators thoroughly should wash and scrub each stallion breeding by natural cover and dry the penis after washing. After the stallion covers the mare, the operator lavages the uterus, infusing the mare with appropriate antibiotics between 4 and 6 hours after breeding.

One can wash stallions with penile colonization by *Klebsiella* or *Pseudomonas* spp. with a weak solution of HCl or sodium hypochlorite. One should avoid systemic treatment because it has proved unrewarding in most cases.[95]

16.10.3.3.2.3

Contagious Equine Metritis.

Contagious equine metritis, caused by the coccobacillus *Taylorella equigenitalis*, is perhaps the only true venereal sexually transmissible disease in horses. Contagious equine metritis, although not present in North America, could be imported, particularly through frozen semen from untested stallions.

Stallions infected with contagious equine metritis are asymptomatic carriers and harbor the organism in the urethral fossa, the urethra, or the sheath. Mares bred to infected stallions develop a severe purulent vaginitis, cervicitis, and endometritis. Infection in these mares appears to resolve, but they remain infected and the organism can be cultured from the clitoral fossa. Diagnosis of contagious equine metritis is by culture of the organism. Aimes medium supplemented with charcoal is recommended for transport of culture specimens. Swabs are plated on Columbia blood-chocolate agar at 37° C and 7%

carbon dioxide. Because of the slow growth of *T. equigenitalis*, the possibility of false-negative results is high.[96]

16.10.3.3.2.4

Internal Bacterial Infections.

Although infections of the accessory sex glands are uncommon, unilateral or bilateral seminal vesiculitis 1155
can occur. Bacterial infection of the seminal vesicles is not accompanied by clinical signs except for 1156
white blood cells in the ejaculate.[7] In some stallions with seminal vesiculitis, the glands may be enlarged, firm, and painful on palpation if the condition is acute. One cannot consider gland size alone and character of seminal vesicle fluid on ultrasound examination as accurate indicators of infection, because the glands vary in size and appearance within individual stallions and across breeds. Diagnosis of seminal vesiculitis is made best by rectal palpation, observation of large numbers of neutrophils in the semen, bacterial culture of semen, and endoscopy of the urethra and seminal vesicles. Direct culture of the seminal vesicles during endoscopy increases the clinician's confidence in the significance of organisms cultured. Treatment is difficult and the prognosis is guarded. Reported treatments include systemic treatment with antibiotics, or alternatively, addition of extenders containing appropriate antibiotics to the semen of the affected stallion. Recently, endoscope-aided direct lavage followed by antibiotic instillation into the vesicular gland lumen has been advocated.

Bacterial infections of the accessory genital glands, epididymides, or testes are uncommon in stallions but are clinically important because of their persistent nature, tendency for venereal transmission, and detrimental effect on fertility of stallions. One usually identifies these infected stallions by the presence of numerous neutrophils in ejaculates, whereas one uses other diagnostic procedures such as ultrasound and endoscopy to localize the site of infection. Treatment generally consists of combining local and systemic therapy.[97]

16.10.3.3.2.5

Viral Diseases.

Although many viruses can affect the reproductive performance of a stallion, only two are considered to be venereally transmissible. Equine herpesvirus 3, the causative agent for equine coital exanthema, and equine arteritis virus (EAV), which is responsible for equine viral arteritis (EVA).

16.10.3.3.2.6

Equine Coital Exanthema.

Equine coital exanthema can be transmitted by the stallion to the mare or from the mare to the stallion. The disease is characterized by the formation of small (0.5- to 1-cm) blisterlike lesions on the penis and prepuce or on the perineal area of the mare. These lesions eventually break to form skin ulcers that usually resolve completely in 3 to 4 weeks, leaving some round white scars in the area that was affected. Sometimes one can observe mild fever and slight depression. The effect on fertility is not known, but stallions and mares during the acute phase of the disease should be rested sexually to avoid further spread of the disease.[91]

16.10.3.3.2.7

Equine Viral Arteritis.

Equine arteritis virus is a small RNA virus that can infect horses and donkeys and is thought to be present in most countries except Iceland and Japan. Presently, EAV is responsible for major restrictions

in the international movement of horses and semen. Although most EAV infections are asymptomatic, acutely infected animals may develop a wide range of clinical signs, including fever, limb and ventral edema, depression, rhinitis, and conjunctivitis. The virus may cause abortion and has caused mortality in neonates. After natural EAV infection, most horses develop a solid, long-term immunity to disease. Mares and geldings eliminate the virus within 60 days, but 30% to 60% of acutely infected stallions become persistently infected and maintain EAV within the reproductive tract, permanently shedding the virus in the semen and efficiently transmitting the virus through the semen.[98] Mares infected venereally may not have clinical signs, but they shed large amounts of virus in nasopharyngeal secretions and in urine, which may result in the lateral spread of infection by an aerosol route.

The consequences of venereally acquired infection are minimal, with no known effects on conception rate, but mares infected at later stages of gestation may abort. Identification of carrier stallions is crucial to control the dissemination of EAV. One can identify these animals by serologic screening using a virus neutralization test. If the test is positive at a titer of 1:4 or higher, one should test the stallion for persistent infection by virus isolation from the sperm-rich fraction of the ejaculate or by test mating. Shedding stallions should not be used for breeding or should be bred only to mares seropositive through natural infection or vaccination that are isolated subsequently from seronegative horses for 3 weeks after natural or artificial insemination.

One of the greatest risks of EAV infection is abortion, which may occur even if the mare had no clinical signs. In cases of natural exposure the abortion rate has varied from less than 10% to more than 60% and can occur between 3 and 10 months of gestation. The abortions appear to result from the direct impairment of maternal fetal support and not from fetal infection.[98]

Although mares and geldings are able to eliminate virus from all body tissues by 60 days after infection, 30% to 60% of stallions become infected persistently. In these animals, virus is maintained in the accessory organs of the reproductive tract, principally the ampullae of the vas deferens and is shed constantly in the semen.[99] Three carrier states exist in the stallion: (1) *a short-term state during convalescence* (duration of several weeks), (2) *a medium-term carrier state* (lasting for 3 to 9 months), and (3) *a long-term chronic condition* that may persist for years after the initial infection. The development and maintenance of virus persistence depends in large part on the presence of testosterone. Persistently infected stallions that were castrated but given testosterone continued to shed virus, whereas those administered a placebo ceased virus shedding. In addition, virus could not be detected in geldings 1156
after 60 days after infection.[16] The ability of a large percentage of stallions to eliminate the virus 1157
effectively in time suggests that differences in the immune response of the host may be involved, or alternatively, virus strains may have biologic differences that influence their ability to persist in the reproductive tract. Establishment of persistence may involve a multifactorial process, with dependence on host and viral factors.[98]

After clinical recovery from initial infection, no significant decrease in the fertility of shedding stallions occurs. Mares infected after service by a carrier stallion do not appear to have any related fertility problems during the same or subsequent years, and no reports indicate mares becoming EAV carriers or chronic shedders or virus passage by the venereal route from a seropositive mare, causing clinical disease or seroconversion in a stallion.[98]

The two major routes by which EAV is spread are *aerosols* generated from secretions (respiratory or urine) from acutely infected animals or from secretions from recent abortions, and *venereal* from semen

from a shedding stallion. Close contact between animals generally is required for efficient virus spread in aerosol transmission. Personnel and fomites may play a minor role in virus dissemination. Virus is viable in fresh, chilled, and frozen semen, and venereal transmission is efficient, with 85% to 100% of seronegative mares seroconverting after being bred to stallions shedding virus. In several cases, outbreaks of clinical disease have been traced to a persistently infected stallion.[99]

Clinically, EVA resembles several other viral infections of horses, and a definitive diagnosis requires laboratory confirmation. One can diagnose acute infections by virus isolation or by serologically identifying a fourfold or greater rise in neutralizing titer between acute and convalescent serum samples. In the case of abortion, one can attempt virus isolation from fetal and placental tissuesor can demonstrate seroconversion in the mare. One can diagnose persistent infection in stallions by first screening serum for antibody in a serum neutralization test. If the serum is seropositive at a titer of 1:4, one should perform virus isolation on the untreated, sperm-rich fraction of the ejaculate or should test-mate the stallion to seronegative mares and monitor them for seroconversion.

The method of choice for antibody detection is the serum neutralization test. Antibody titers develop 2 to4 weeks following infection, are maximal at 2 to 4 months, and remain stable for several years. A titer of 1:4 or greater in duplicate sera is considered EAV seropositive. One must test semen from a seropositive stallion to determine the EVA status of the stallion as a carrier.[100] The current test for identifying virus in tissues and semen is virus isolation in cell culture. In EAV related-abortion, the fetus and placenta contain large amounts of virus. One should collect samples of placenta, spleen, lung, and kidney along with fetal and placental fluids in a sterile manner as soon as possible after the abortion occurred, chill the samples on ice, and submit them for virus isolation. One should obtain blood from the mare at the time of the abortion and 3 weeks later for testing by serum neutralization.[98]

After having determined that a stallion is seropositive at a titer of 1:4 in a serum neutralization test, one should collect a semen sample using an AV or a condom and a phantom or a teaser mare. If this is not possible, one can collect a dismount sample at the time of breeding; however, this is less satisfactory. The sample should be from the sperm-rich fraction of the full ejaculate and should be chilled immediately and shipped at 4° C to arrive at the diagnostic facility within 24 hours. If this is not possible, one should freeze the sample at below –20° C and ship it to the diagnostic facility under these conditions. Submission of two samples, collected the same day or on consecutive days is recommended. One should avoid washing the penis with antiseptics or disinfectants before collection of the samples. Samples of commercial frozen semen also may be tested, but the sample must have at least 2 billion sperm cells to be representative. False negatives have been reported because of the lack of seminal plasma in cryopreserved semen.[99]

16.10.3.3.2.8

Prevention and Control of Equine Viral Arteritis.

A modified live (ARVAC, Fort Dodge, Iowa) and a formalin-inactivated (ARTERVAC, Fort Dodge, Iowa) vaccine are available. Both vaccines induce virus-neutralizing antibodies, the presence of which correlates with protection from disease, abortion, and the development of persistent infection. EAV has a worldwide distribution and its prevalence is increasing. As a consequence, an increasing number of EVA outbreaks are being reported. The trend is likely to continue unless action is taken to slow or halt the transmission of this agent through semen. The modified live virus vaccine (ARVAC) does not produce any adverse effects in stallions apart from a possible short-term abnormality of sperm morphology and a mild fever with no overt clinical signs. However, one can isolate live virus

sporadically from the nasopharynx and blood after modified live virus vaccination. Serum neutralization antibody titers are induced within 5 to 8 days and persist for at least 2 years. The modified live virus protects against clinical disease and reduces the amount of virus shed from the respiratory tract in experimental infection. Horses in contact with and mares served by vaccinated stallions are not infected by EAV, and vaccinated mares experimentally challenged by artificial insemination are protected from clinical disease, but not infection. In the field the modified live virus vaccine has been used to control EAV outbreaks in some states of the United State since 1984, but the vaccine is not licensed worldwide. [96]

EVA is entirely preventable if horse owners, breeders, and barn managers follow simple 1157 serosurveillance and hygiene procedures. Controlling the dissemination of EAV requires a concerted 1158 effort on the part of all those involved in the equine industry. The presence of neutralizing antibody that correlates well with protection from disease, abortion, and the development of persistent infection in stallions is evidence that control programs, once instituted, have been successful.

16.10.3.3.2.9 Protozoal Diseases

Trypanosoma equiperdum is the causative agent for dourine, or mal du coit. The organism is not present in the United States or Europe but is still endemic in Africa and some areas in Asia and South America. *T. equiperdum* is perhaps the only protozoal organism that can be transmitted venereally. Tentative diagnosis is by the clinical manifestation of the disease, which includes intermittent fever, depression, progressive loss of body condition and severe purulent discharge from the urethra. Definitive diagnosis is by complement fixation and culture.[96]

Other microorganisms with the potential to be transmitted venereally include *Chlamydia* spp. and *Mycoplasma* spp. Although both of these organisms have been isolated from the urethra of stallions, their effect on equine fertility is not well known. One must be aware of the possibility of these agents causing infertility in mares and stallions. *Candida* spp and *Aspergillus* spp., although not commonly present in semen or the genital tract of the stallion, can be potential pathogens, particularly in artificial insemination programs in which the hygiene of the collection and processing equipment is not well monitored.

16.10.3.3.2.10 Genetic Diseases

One of the main reasons for stallions standing at stud is to pass on to their offspring their genetic attributes. However, sometimes stallions can be carriers of a hereditary condition that may be expressed in his foals when he is mated to certain mares. Perhaps the clearest example of the potential effect of the genetic effect is the “Impressive Syndrome” of American Quarter Horses, in which thousands of mares were bred by one stallion transmitting the gene for hyperkalemic periodic paralysis.

Conditions such as genetic mosaics (63 XO/64 XY or 65 XYY), certain sperm defects such as detached heads, or midpiece defects and testicular characteristics such as small testicular size or premature testicular degeneration are or could be transmitted genetically.

Other conditions that have been proved to have or are suspected of having a hereditary basis include combined immune deficiency in Arabians, umbilical and scrotal herniae, parrot mouth, cryptorchidism, and testicular rotation. The expression of any of these genetic traits can have profound and devastating

effects on a breeding program. When one suspects a condition, one must use cytogenetic or molecular diagnostic procedures to identify undesirable traits that will be expressed in the adult animal.

The pivotal point in prevention and control of infectious disease is the identification of infected stallions and mares and the institution of management procedures to prevent the further spread of any disease to susceptible populations through the breeding of mares by natural service or artificial insemination. If a stallion proves tobe a carrier, he should not be used for breeding through natural service or his semen should be treated with proper antibiotics in cases of bacterial disease. In the case of EVA, stallions might still be used, provided that the mare owners are informed that the stallion is a shedder so that they can take the preventive measurements such as vaccinating the mares.

The option to use a particular stallion in a breeding facility may depend on the value of the stallion as a breeding animal and individual regional regulations. Whatever the case may be, all stallions should have a diagnosed status before each breeding season. Breeding managers and stallion owners must be aware that poor genital hygiene of a breeding stallion and of the maresat the time of breeding greatly increases the chances of spreading disease from a stallion to a group of maresor from a mare to a stallion. Poor management with poor breeding records and poor hygiene at the time of breeding are perhaps the most common reasonsfor venereal diseases causing severe and irreversible problems in a breeding operation.

16.10.4 Pathologic Conditions of the Reproductive Tract

Clinicians must be able to recognize pathologic conditions accurately to make sound decisions respecting the therapy and management of stallions. Acquired conditions may be reversible by surgical or other therapeutical means, but diagnosis of irreversible or terminal conditions must be well substantiated because the conditions could have a significant effect on the economics of a breeding operation. One also must take into account ethical considerations because some genetic diseases could have a significant effect on the breed as a whole.

16.10.4.1 CONGENITAL DEFECTS

For an individual to develop into a normal male the Y chromosome must be expressed. Horses with genetic abnormalities can vary in their genotype, anatomic features, and behavior.[101] The most common causes of congenital defects are hermaphroditism, XY sex reversal, and testicular feminization or androgen insensitivity.

Hermaphrodites are classified based on the type of gonadal tissue present. *True hermaphrodites* have testicular and ovarian tissue,[101] whereas *pseudohermaphrodites* have testes (male pseudohermaphrodites) or 1158
ovaries (female pseudohermaphrodites), with various combinations of male and female internal reproductive 1159
organs.[102–105] Perhaps the most common of the intersexes is the male pseudohermaphrodite. For the veterinarian to examine a “mare” with a small vulva and an extremely large clitoris or what appears to be a glans penis is not uncommon. Behavior in these animals most likely depends on the gonadal tissue present.

Horses with XY sex reversal syndrome are characterized by female external genitalia but a normal 64XY karyotype.

Androgen insensitivity or testicular feminization syndrome is a well-characterized genetic disease in human beings and in some domestic species. Animals have a normal XY karyotype and male behavior but female genotype. The syndrome has two possible causes: a mutation at the level of the gene that codes for the androgen receptor or a deficiency in 5α-reductase, the enzyme responsible for conversion of testosterone

tothe active androgen dihydrotestosterone.[104] In either situation the reproductive tract is underdeveloped and only external female genitalia are present.

One can diagnose genetic defects tentatively by visual inspection of the external genitalia, rectal palpation, and ultrasonography. However, one can reach a definitive diagnosis only by cytogenetic evaluation. One must submit blood samples in tubes with EDTA anticoagulant to the appropriate laboratory.

16.10.4.2 DISEASES OF THE SCROTUM

The scrotum in the horse is a pliable and thin-skinned pouch with a fine layer of short hair, numerous sweat glands, and the thick muscle layer (dartos). The scrotum is usually darkly pigmented. Functional integrity of the scrotum is vital because it is perhaps the most important structure regulating testicular temperature.[106] Abnormal conformation, absence, or increase in thickness can have a dramatic effect on spermatogenesis. The scrotum is easy to access for examination by visual inspection and palpation. The absence of the scrotum or an extremely small scrotum in most instances indicates genetic abnormalities such as bilateral cryptorchidism or intersex conditions. One should record increases in the thickness of the scrotal wall, surface irregularities, or changes in color of the skin. Lesions of the scrotum can be physical or infectious in origin.

16.10.4.2.1 Physical Problems

Traumatic insults to the scrotum or the scrotal area and other inflammatory processes in the genital area often result in scrotal edema. The clinician must identify the cause or possible causes of the swelling to initiate adequate therapy. Chronic edema of the scrotum can result in abrasions or secondary lacerations and can be complicated further by cutaneous bacterial contamination. Differential diagnoses for scrotal swelling include systemic infectious processes, scrotal herniae, spermatic cord torsion, or hemorrhagic processes associated with the testicles or spermatic cords. One must be sure not to confuse primary edema of the scrotum with peritoneal fluid accumulation between the vaginal and parietal tunics of the testicle.[107] One can use ultrasonographic examination or fine needle aspiration for the differential diagnosis.

One should direct therapy of scrotal edema toward removing the primary cause and controlling the inflammation with supportive therapy. Antiinflammatory drugs, diuretics, and frequent cold-water therapy are measures aimed at reestablishing the circulation in the area. If the skin is broken, one should institute broad-spectrum antibiotic therapy. Gentle and continuous lubrication of the scrotum with emollients and a tetanus toxoid booster are recommended. Depending on the degree of involvement, unilateral or bilateral orchiectomy also may be indicated.[107]

16.10.4.2.2 Infectious Causes

16.10.4.2.2.1 Viral Causes

Equine infectious anemia or diseases causing severe hypoproteinemia can cause scrotal edema. Hypoproteinemia is confirmed by analyzing levels of total protein in serum. One can demonstrate the presence of the equine infectious anemia virus by agar gel immunodiffusion or Coggins test.

During the acute phase of EVA, males often display different degrees of lower abdominal edema that may involve the scrotum.

Neoplastic conditions of the scrotum that have been reported include melanomas and sarcoids. Melanomas have the characteristics of benign tumors of the dermis and epidermis but may become metastatic in somehorses. Sarcoids are common nonmetastatic skin tumors. One diagnoses both conditions by their general appearance and makes definitive diagnosis by histologic sections.[107]

16.10.4.2.2.2 Parasitic Causes

Although *Trypanosoma equiperdum*, the causative agent of *dourine*, is not present in North America, scrotal edema is a typical sign of the initial phases of this venereally transmitted disease.

Onchocerca cervicalis, a microfilaria, and summer sores caused by *Habronema* sp. are seldom a cause of scrotal dermatitis. These infections are transmitted by several species of flies and mosquitoes. Ivermectin therapy at regular intervals is recommended for treatment of these conditions.[108]

16.10.4.2.2.3 Bacterial Causes

Scrotal infections most often result from secondary breaks in the skin caused by castrations, traumatic lacerations, or puncture wounds. Less often, infections of the scrotum can result from septic processes in the testis or peritoneum.[107] In addition to appropriate antibiotic therapy, one should implement 1159
continuous washing of the infected area, antiinflammatory drugs, and supportive therapy. 1160

16.10.4.3 DISEASES OF THE TESTES

The four major cell types of the testis are Sertoli's, Leydig's, myoid, and germ cells. During the last month of gestation or first month of life in the normal horse, the gonads migrate through the inguinal canal into the scrotum. Because of this migration the testis is surrounded by the *tunica vaginalis* or peritoneum and the *tunica albuginea* or the capsule proper.

Sexual developmental abnormalities often are expressed as testicular problems. Among the congenital testicular defects that have been reported in stallions are *monorchidism, anorchidism*, and *polyorchidism*, which are the absence of one or both testicles or the presence of more than two testes, respectively.[109]

16.10.4.3.1 Ectopic Testis

A gonad that fails to reach the scrotum and deviates from the normal path of descent is termed an *ectopic testis*. These testes may be subcutaneous in the inner thigh or abdominal or perineal region. Some authors report splenic-testicular fusion on the left side.

16.10.4.3.2 Cryptorchidism

In a cryptorchid animal, one or both testicles are in an ectopic location for an adult animal, although the gonads remain in the normal path of testicular descent. Cryptorchid testes may be abdominal or inguinal.

Because of the complexity of the process of testicular descent, the exact mechanism for the failure of normal gonadal migration is not well understood. Although cryptorchidism has been speculated to be a hereditary condition, none of 56 colts sired by a cryptorchid Quarter Horse had abnormalities in their testicular descent. If the condition is heritable, perhaps a gene with low penetrance controls the process or is associated with several autosomal genes, as has been shown in men. The incidence of the condition according to Stickle and Fessler[110] and Hayes[111] is believed to be between 15% and 20%. Prevalence is higher in Percherons, followed by Palominos and Quarter Horses. Prevalence in Thoroughbreds is lower than in other breeds.

One can diagnose the unilateral cryptorchid horse easily by palpation of the scrotal contents and the inguinal region. When the testis is closer to the internal inguinal ring, in an abdominal or ectopic location, diagnosis can be difficult. Although frequently unrewarding, rectal palpation and ultrasonography are used as diagnostic aids. The experienced clinician can locate the testis and epididymis in or around the internal inguinal ring just cranial to the pelvic brim slightly off the midline. When palpation and ultrasonography have failed to identify testicular tissue, one should perform hormonal assays. Circulating testosterone and estrone sulfate levels are of great diagnostic value. Because of the variation in baseline testosterone levels, one should measure the hormone after stimulation with 5000 to 10,000 IU of human chorionic gonadotropin.

Collection of serum samples immediately before stimulation and 30 and 60 minutes or 60 minutes and4 hours after the injection is recommended. A twofold to threefold increase in the level of testosterone is diagnostic for testicular tissue. Although false-positive results are rare, false-negative results can occur in 5% to 10% of horses. A single measurement of estrone sulfate has been reported to be highly accurate for diagnosis of the condition in adult cryptorchids. In very young equids, one should interpret low hormonal levels carefully because false-negative results may be more common than in adult horses. The treatment for the condition is invariably castration.

16.10.4.3.3

Gonadal Hypoplasia

Small testes may result from a number of underlying complex processes such as spermatogenic arrest and germ cell deficiencies. Testicular hypoplasia is the failure of the gonads to reach their full adult size and must be differentiated from gonadal atrophy or testicular degeneration, which is the reduction in testicular size after the gonad has reached full adult size. The cause of the hypoplastic gonad is complex and is thought to be congenital or acquired. Although not clear for horses, a genetic component has been identified in other species.[112] In general, testicular hyperthermia, malnutrition and endocrine imbalances particularly in steroid-treated young stallions can affect testicular size negatively. One must remember that the testicles do not start developing before 15 to 18 months and continue to increase in size until the age of 4 to 5 years. One should not confirm testicular hypoplasia before the stallion is 2 to 3 years old. One should discourage the breeding of mares to stallions with hypoplastic gonads; however often because of the value or the performance record, animals with small testicular size are used at stud. In these cases, implementation of managerial practices to maximize the reproductive performance of the animal is important and should include reducing the number of mares in the book and breeding mares only once close to ovulation.

16.10.4.3.4

Gonadal Atrophy

Also known as testicular degeneration, gonadal atrophy is found most commonly in the mature stallion and isa consequence of the disruption of the process of spermatogenesis. One must differentiate atrophy and hypoplasia. A thorough reproductive examination and an accurate history are fundamental in 1160
differentiating the two conditions. One should note inconsistencies between sperm output and testicular 1161
size and patterns of agglutination of the sperm cells. Small testicular size in relation to the epididymis indicates atrophy. However, developmental abnormalities such as a small penis and enlarged inguinal rings associated with small testicular size often indicate hypoplasia. The veterinarian should know that atrophy or degeneration is an acquired condition thatin some cases is reversible.

Testicular atrophy is caused most commonly by administration of anabolic steroids or other products such as altrenogest to colts or stallions during their racing or show careers. Although the negative effects of steroids on testicular function are considered to be reversible, a between length of exposure and age of administration is suspected. Colts injected with anabolic steroids during their first year of life are at greater risk of having permanent damage of the testicular parenchyma. The detrimental effects on spermatogenesis are caused by an increase in the circulating levels of androgens, which in turn havea negative feedback on LH secretion by the pituitary with a consequent decline in endogenous testosterone. The reduction of endogenous testosterone reduces testicular function with a significant reduction in sperm production.

Hyperthermia caused by prolonged recumbency; trauma; torsions; infections with disruption of the blood-testis barrier and the consequent production of antisperm antibodies; inappropriate or prolonged steroid therapy especially with testosterone or anabolic steroids; accumulations of fluids such as in hydroceles; and advanced age have been implicated as possible causes of testicular degeneration. Scrotal lesions that impair the normal testicular thermoregulation may be a significant factor causing gonadal atrophy. Other causes of testicular degeneration include radiation exposure; nutritional disorders, particularly those of vitamin A and zinc; and toxicity with heavy metals or nitrogen, phosphorus, and halogenated compounds.

In the initial phases of testicular degeneration, the testis feels softer. As the process becomes more chronic, the testicular tissue is replaced by connective tissue, making the testis feel firmer on palpation.
